## $\text{Ag}_{1.2}\text{Sn}_{0.9}\text{Sb}_3\text{S}_6$ , a tin-bearing andorite phase

ANDORITE is considered to be a relatively common Ag-sulphosalt mineral, and in some deposits it forms the chief silver ore (Chace, 1948). By substitution between 2Pb and Ag+Sb or 3Pb and 2Sb + □, andorite shows compositional variations from its formula  $\text{PbAgSb}_3\text{S}_6$  (Nuffield, 1945; Mozgova *et al.*, 1983). In the system  $\text{Ag}_2\text{S-PbS-Sb}_2\text{S}_3$ , andorite displays an extensive range of solid solution at temperatures between 300 and 500 °C (Hoda

and Chang, 1975). An andorite-like phase was synthesized in the study of reactions of silver sulphantimonides and tin sulphides (Chang, 1983). The purpose of this investigation is to examine its stability in the system  $\text{Ag}_2\text{S-SnS-Sb}_2\text{S}_3$ , and its relations to andorite.

*Experimental procedures.* Experiments were performed by means of the conventional evacuated glass capsule technique using specpure elements

(Pb, Sn, Sb, and S) and pure sulphide ( $\text{Ag}_2\text{S}$ ). Heat treatment was conducted in muffle furnaces controlled to  $\pm 3^\circ\text{C}$ . Quenched products were examined by X-ray powder diffraction and reflected-light microscopy. Chemical compositions of selected samples were determined by microprobe analysis. A peak stripping technique was used to compensate for the line overlaps of Sb and Sn. Cell dimensions of  $\pm 0.02 \text{ \AA}$  were computed by using a least-squares refinement program.

**Phase relations in the system  $\text{Ag}_2\text{S}$ - $\text{SnS}$ - $\text{Sb}_2\text{S}_3$ .** A pair of intermediate phases is known to exist in each of the binary systems  $\text{Ag}_2\text{S}$ - $\text{Sb}_2\text{S}_3$  and  $\text{SnS}$ - $\text{Sb}_2\text{S}_3$ , whereas the system  $\text{Ag}_2\text{S}$ - $\text{SnS}$  has a simple eutectic relationship.  $\text{AgSbS}_2$  and  $\text{Ag}_3\text{SbS}_3$  melt congruently at 520 and  $485^\circ\text{C}$ , respectively, and the system  $\text{Ag}_2\text{S}$ - $\text{Sb}_2\text{S}_3$  becomes completely solidified when the liquid phase on the antimony-rich side terminates at  $450^\circ\text{C}$  (Keighin and Honea, 1969).  $\text{SnSb}_2\text{S}_4$  melts incongruently at  $493^\circ\text{C}$  to liquid and  $\text{Sn}_3\text{Sb}_2\text{S}_6$ , which in turn melts incongruently at  $565^\circ\text{C}$  to liquid and  $\text{SnS}$  (Sachdev and Chang, 1975). Both  $\text{SnSb}_2\text{S}_4$  and  $\text{Sn}_3\text{Sb}_2\text{S}_6$  are orthorhombic with  $a = 25.641$ ,  $b = 20.381$ , and  $c = 3.8973 \text{ \AA}$  (Smith and Parise, 1985) and  $a = 23.18$ ,  $b = 3.965$ , and  $c = 34.93 \text{ \AA}$  (Smith, 1984), respectively.

Phase relations based on experimental data in the system  $\text{Ag}_2\text{S}$ - $\text{SnS}$ - $\text{Sb}_2\text{S}_3$  at  $400^\circ\text{C}$  are illustrated in Fig. 1. The system is divided into two halves by the join  $\text{AgSbS}_2$ - $\text{SnS}$ , along which mutual solid solutions exist.  $\text{AgSbS}_2$  at  $400^\circ\text{C}$  has the NaCl-type structure, and its solid solution extends to  $\text{Ag}_{0.9}\text{Sn}_{0.2}\text{Sb}_{0.9}\text{S}_2$ . The solid solution of  $\text{SnS}$  has a range to  $\text{Ag}_{0.1}\text{Sn}_{0.8}\text{Sb}_{0.1}\text{S}$ .

FIG. 1. Phase relations in the system  $\text{Ag}_2\text{S}$ - $\text{SnS}$ - $\text{Sb}_2\text{S}_3$  at  $400^\circ\text{C}$ . Symbols used are solid triangle, three phases; half-filled circle, two phases; and solid circle, one phase.

The andorite-like phase (Chang, 1983) is stable in the system, and forms equilibrium assemblages with  $\text{SnS}$ ,  $\text{Sn}_3\text{Sb}_2\text{S}_6$ ,  $\text{SnSb}_2\text{S}_4$ ,  $\text{Sb}_2\text{S}_3$ , and  $\text{AgSbS}_2$ . Its composition,  $\text{Ag}_{1.2}\text{Sn}_{0.9}\text{Sb}_3\text{S}_6$ , falls on the join  $\text{AgSbS}_2$ - $\text{SnSb}_2\text{S}_4$ , and correlates well with the composition of andorite,  $\text{AgPbSb}_3\text{S}_6$ . The substitution involves the following exchange:  $\text{Ag}_{1.2} + \text{Sn}_{0.9} = \text{Ag}_{1.0} + \text{Pb}_{0.1}$ .  $\text{Ag}_{1.2}\text{Sn}_{0.9}\text{Sb}_3\text{S}_6$  melts congruently at  $433 \pm 2^\circ\text{C}$ , and has eutectic relations with  $\text{AgSbS}_2$  and  $\text{AnSb}_2\text{S}_4$ . The eutectic temperatures determined in both relations are  $427 \pm 2^\circ\text{C}$ . The difference, if there is one, between them cannot be detected because the temperature range involved is very small. The compositions at the eutectic points are 45 and 57 mole%  $\text{SnSb}_2\text{S}_4$ .

**Phase relations of tin-bearing andorite and andorite.** A complete solid solution series exists between the tin-bearing andorite phase ( $\text{Ag}_{1.2}\text{Sn}_{0.9}\text{Sb}_3\text{S}_6$ ) and andorite ( $\text{AgPbSb}_3\text{S}_6$ ) as shown in Fig. 2 with melting points ranging from  $433$  to  $506^\circ\text{C}$ . The curvature of the concave liquidus is greater than that of the solidus, which in fact has a tendency to become concave, resulting in an inflected curve. This feature suggests that andorite has a larger heat of fusion. The cell dimensions of this series vary within a very small range from  $a = 13.04$ ,  $b = 19.17$ , and  $c = 4.29 \text{ \AA}$  for andorite to  $a = 12.89$ ,  $b = 19.15$ , and  $c = 4.22 \text{ \AA}$  for tin-bearing andorite.

FIG. 2. Phase relations between tin-bearing andorite and andorite.

**Non-occurrence of natural tin-bearing andorite.** No tin-bearing andorite has been reported in nature. In the tin district of Bolivia, where andorite is the most abundant silver sulphosalt in the cassiterite-sulphide deposits, chemical analyses show the presence of Fe, Cu, and Zn in andorite

(Nuffield, 1945), but no Sn was reported. At Dachang, China, another cassiterite-sulphide deposit, andorite in a much restricted occurrence has a composition of  $\text{Ag}_{0.96}\text{Pb}_{1.27}\text{Sb}_{3.03}\text{S}_6$  containing no tin (Huang, 1985). It appears that in these deposits the Sn present in the ore-forming environment formed tin minerals at relatively high temperatures, while andorite is a product of late-stage processes at lower temperatures. Recent analyses of andorite from various occurrences (Borodaev *et al.*, 1971; Birch, 1981; Makovicky and Mumme, 1983 and Moelo, 1983) all show an absence of Sn.

## An unusual form of coated diamond

SOME naturally occurring diamonds have an outer layer which is somewhat opaque and coloured. These diamonds are known in the trade as coated diamonds, and are of some interest as their unprepossessing exterior may conceal a core of good quality diamond (Bruton, 1970; Copeland, 1960; Custers, 1950; Lonsdale and Milledge, 1965; Orlov, 1977). Generally they are easily recognized by their lack of transparency, apparently arising from the presence of some impurities. Other methods of inspection reveal fundamental differences in the structure of core and coat. X-ray topographs commonly indicate the presence of patterns of structure in the core formed by growth on {111} planes, whereas the patterns in the coat are quite different, and suggestive of some form of radial growth (Kamiya and Lang, 1965; Machado *et al.*, 1985). Coated diamonds also show very characteristic behaviour when viewed in the cathodoluminescent mode (CL) of the SEM, the luminescence of coat and core differing greatly both in form and intensity.

We have recently examined seven natural colourless diamonds of gem quality from Zaire. They are of dodecahedral form and exhibit some vestigial {111} surfaces which permit a view into the interior of the stone. Visual and microscopic inspections of these diamonds gave no suggestion that the crystals were of other than uniform composition. However, on polishing an (001) surface on one of them (A52) for an experiment to be described elsewhere, a marked step was observed on the surface between the central and outer regions; see Fig. 1, an optical micrograph taken with Nomarski technique. The stone was then examined by X-ray topography and in the SEM. Fig. 2, a section topograph of this diamond shows a central pattern of growth typical of perhaps most diamonds, and an outer radial pattern similar to that observed in coated stones. Fig. 3 shows micrographs of the same diamond taken in the CL mode of the SEM with exposure chosen to bring out detail of the coat and core respectively. Note in particular the absence of linear growth lines in the coat and the indications
