# Zektzerite, $\mathrm{NaLiZrSi} \mathrm{O}_{15}$ : a silicate with six-tetrahedral-repeat double chains 

Subrata Ghose and Che'ng Wan<br>Department of Geological Sciences, University of Washington<br>Seattle, Washington 98195

#### Abstract

Zektzerite, $\mathrm{NaLiZrSi}_{6} \mathrm{O}_{15}$, is orthorhombic, space group Cmca, with cell dimensions: $a=$ $14.330(2), b=17.354(2)$, and $c=10.164(2) \mathrm{A} ; Z=8$. The crystal structure has been determined by the symbolic addition method and refined by the method of least squares to an $R$ factor of 0.040 for 2389 reflections, measured on an automatic single-crystal diffractometer.

The crystal structure of zektzerite is a three-dimensional framework consisting of (a) edgesharing Na-polyhedral chains, (b) octahedral-tetrahedral chains, formed by alternating Li tetrahedra and Zr octahedra sharing edges, and (c) corrugated double-silicate chains with sixtetrahedral repeat (Sechser-Doppelkette) and three different four-membered rings. The Li tetrahedron, with an average Li-O distance of 1.959 A , shows strong angular distortion. The Zr octahedron is nearly regular, with an average $\mathrm{Zr}-\mathrm{O}$ distance of 2.074 A . The sodium atom occurs in an irregular cavity formed by the corrugation of the silicate double chains; it is coordinated to six oxygen atoms at distances of $2.37-2.67 \mathrm{~A}$, and four more oxygen atoms at distances of $3.12-3.23 \mathrm{~A}$. The average $\mathrm{Si}-\mathrm{O}$ bond lengths within the $\mathrm{Si}(1), \mathrm{Si}(2)$, and $\mathrm{Si}(3)$ tetrahedra are $1.614,1.616$, and 1.610 A . The Si-O-Si bond angles involving oxygens lying on mirror planes average $155.7^{\circ}$, whereas those within the single silicate chain average $147.6^{\circ}$. The larger Si-O-Si angles are associated with shorter Si-O bonds. Zektzerite is isostructural with tuhualite, $(\mathrm{Na}, \mathrm{K}) \mathrm{Fe}^{2+} \mathrm{Fe}^{3+} \mathrm{Si}_{6} \mathrm{O}_{15}$, and synthetic $\mathrm{Na}_{2} \mathrm{Mg}_{2} \mathrm{Si}_{6} \mathrm{O}_{15}$. Provided the valence balance and coordination requirements are satisfied, a large number of silicates can crystallize within this structure type.

## Introduction

Zektzerite, $\mathrm{LiNaZrSi}_{6} \mathrm{O}_{15}$, a new mineral found in miarolitic cavities of the Golden Horn batholith near Washington Pass, North Cascades, Washington, occurs in association with quartz, microcline, aegirine, riebeckite, astrophyllite, zircon, and elpidite. It is orthorhombic and occurs as translucent colorless stout prisms. Dunn et al. (1977) determined its optical properties, unit-cell dimensions and possible space groups; they also noted the similarity of its cell dimensions and chemical composition with those of tuhualite, $(\mathrm{Na}, \mathrm{K})_{2} \mathrm{Fe}_{2}^{2+} \mathrm{Fe}_{2}^{3+} \mathrm{Si}_{12} \mathrm{O}_{30} \cdot \mathrm{H}_{2} \mathrm{O}$. The present structure determination shows that these two minerals are indeed isostructural, containing double silicate chains with six-tetrahedral repeat (Sechser-Doppelkette). ${ }^{1}$

[^0]
## Experimental

A sphere with a diameter of 044 mm was ground from a single crystal fragment using a sphere grinder (Bond, 1951). The single-crystal sphere was mounted on the computer-controlled automatic single-crystal X-ray diffractometer (Syntex Pī), and the unit-cell dimensions were refined by the method of least squares, using 15 reflections measured with $\mathrm{Mo} K \alpha$ radiation with $2 \theta$ values between $30^{\circ}$ and $40^{\circ}$ (Table 1). The unit-cell dimensions are in good agreement with those determined by Dunn et al. (1977). The intensities of all reflections within a $2 \theta$ value of $65^{\circ}$ were measured on the diffractometer, using $\mathrm{Mo} K \alpha$ radiation monochromatized by reflection from a graphite "single" crystal, and a scintillation counter. A variable scan rate was used, the minimum being $2^{\circ} / \mathrm{min}(50 \mathrm{kV}, 12.5 \mathrm{~mA})$. Out of a total 2389 reflections, 316 were below $3 \sigma(I)$, where $\sigma(I)$ is the standard deviation of the measurement of the intensity, $I$,

as derived from the counting statistics. The intensity data were corrected for Lorentz and polarization factors. No absorption corrections were made, since the linear absorption coefficient of zektzerite for MoK $\alpha$ radiation is small (Table 1).

## Determination and refinement of the crystal structure

Dunn et al. (1977) could not distinguish between the two possible space groups Cmca and C2ca. The Wilson statistics of the measured intensities indicated the presence of a center of symmetry and Cmca as the correct space group. The crystal structure was determined directly by the symbolic addition method (Karle and Karle, 1966), using the computer program Multan (Germain et al., 1971). The first E-map showed the positions of the sodium, zirconium, two silicon, and seven oxygen atoms. Structure-factor cal-
culation based on these atoms followed by difference Fourier synthesis yielded the positions of one silicon and two oxygen atoms. These atomic positions were refined by the method of least squares. The difference Fourier synthesis subsequently calculated revealed the position of the lithium atom.

All the atomic positional and thermal parameters were refined by the method of full-matrix least squares using the Rfine program (Finger, 1969). The observed structure factors ( $F_{\mathrm{o}}$ 's) were weighted by $1 /$ $\sigma^{2}\left(F_{o}\right)$, where $\sigma\left(F_{o}\right)$ is the standard deviation of $F_{o}$, as determined by the counting statistics. The atomic scattering factors for $\mathrm{Li}, \mathrm{Na}, \mathrm{Zr}, \mathrm{Si}$, and O were taken from Cromer and Mann (1968), and corrected for anomalous dispersion (Cromer and Liberman, 1970). Three cycles of refinement using anisotropic temperature factors yielded a final $R$-factor of 0.040 for all reflections. 40 strong low-angle reflections (with $F_{o}$ $F_{c}>10.0$ were believed to be suffering from extinction and were excluded from the refinement. The refinement converged at this stage, the average shift $v s$. error being 0.00 . The final atomic positional and thermal parameters are listed in Table 2. Observed and calculated structure factors are listed in Table 3. ${ }^{2}$ The bond lengths and angles, and the dimensions of

the thermal ellipsoids with their standard deviations were calculated using the program Error (Finger, 1972, private communication). The bond lengths and angles are listed in Table 4 and the dimensions of thermal ellipsoids in Table 5. The average standard deviation in $\mathrm{Li}-\mathrm{O}, \mathrm{Na}-\mathrm{O}, \mathrm{Zr}-\mathrm{O}$, and $\mathrm{Si}-\mathrm{O}$ bond lengths are $0.004,0.002,0.001,0.002 \mathrm{~A}$ and in $\mathrm{O}-\mathrm{Li}-$ $\mathrm{O}, \mathrm{O}-\mathrm{Na}-\mathrm{O}, \mathrm{O}-\mathrm{Zr}-\mathrm{O}$, and $\mathrm{O}-\mathrm{Si}-\mathrm{O}$ angles $0.20,0.05$, $0.06,0.09^{\circ}$ respectively.

## Description of the structure

The crystal structure of zektzerite is a three-dimensional framework, consisting of three types of poly-
hedral chains: (a) an edge-sharing Na polyhedral chain; (b) an octahedral-tetrahedral chain, formed by alternating $\mathrm{LiO}_{4}$ tetrahedra and $\mathrm{ZrO}_{6}$ octahedra sharing edges; and (c) a corrugated silicate double chain, with six-tetrahedral repeat (Sechser-Doppelkette) (Figs. 1 a,b,c).

## The Na polyhedral chain

The sodium atoms occur within cylindrical channels, formed by the corrugation of the silicate double chains (Fig. 2). Of the ten $\mathrm{Na}-\mathrm{O}$ bonds within 3.25A, six are comparatively short, ranging from 2.368A to 2.667 A , forming a highly distorted octahedron;

Table 5. Zektzerite: thermal ellipsoids (standard deviations in parentheses)

within the octahedron, the $\mathrm{O}-\mathrm{Na}-\mathrm{O}$ angles range from $58.2^{\circ}$ to $117.6^{\circ}$. Four longer $\mathrm{Na}-\mathrm{O}$ bonds ranging from 3.120 A to 3.225 A complete the Na polyhedron. Each Na polyhedron shares two opposite edges $\left[\mathrm{O}(1)-\mathrm{O}\left(1^{\prime}\right)\right]$ with two adjacent Na polyhedra to form a chain parallel to the $c$ axis (Fig. la).

## The octahedral-tetrahedral chain

The Li tetrahedron shares two opposite edges $\left[\mathrm{O}(2)-\mathrm{O}\left(4^{\prime}\right) 2.742 \mathrm{~A}\right]$ with two Zr octahedra on either side, thereby forming a chain parallel to the $c$ axis,
with alternating $\mathrm{LiO}_{4}$ tetrahedral and $\mathrm{ZrO}_{6}$ octahedra (Fig. 1b). Within the chain the $\mathrm{Li}-\mathrm{Zr}$ distance is 2.965 A . The Li-O distances (av. 1.959A) within the $\mathrm{LiO}_{4}$ tetrahedron show very little variation, whereas the $\mathrm{O}-\mathrm{Li}-\mathrm{O}$ angles show a large variation, ranging from $88.9^{\circ}$ to $133.3^{\circ}$. The Zr octahedron is nearly regular, the $\mathrm{Zr}-\mathrm{O}$ distances varying from 2.056 to 2.091 A (av. 2.074 A ), and the $\mathrm{O}-\mathrm{Zr}-\mathrm{O}$ angles from $82.4^{\circ}$ to $95.6^{\circ}$. It shares one edge $\left[\mathrm{O}(6)-\mathrm{O}\left(6^{\prime}\right)\right.$ 2.827 A ] with an adjacent Na polyhedron.

The corrugated double-silicate chain with six-tetrahedral repeat

The most interesting part of the structure is the corrugated silicate chain with six-tetrahedral repeat parallel to the $c$ axis. Such a single silicate chain is connected to an identical chain across a mirror-plane by sharing corners, giving rise to a double-silicate chain (Sechser-Doppelkette). These double chains contain three different four-membered tetrahedral rings (Fig. 1c).

## The three-dimensional framework

Each octahedral-tetrahedral chain is connected to four adjacent silicate double chains by sharing corners. Likewise, each silicate double chain is connected to four adjacent octahedral-tetrahedral chains by corner-sharing. The Na polyhedral chains are connected to a pair of silicate double chains on the one side and an octahedral-tetrahedral chain on the other by sharing polyhedral edges and corners. A threedimensional framework structure is formed in this fashion (Fig. 2). The two good cleavages $\{100\}$ and $\{010\}$ break the cation-oxygen bonds, leaving the silicate double chains intact (cf. amphiboles).

## Anisotropic thermal vibration

The thermal vibration of the zirconium and the silicon atoms are nearly isotropic, whereas that of the lithium atom can be represented by a slightly oblate spheroid (Fig. Ib). Commensurate with its environment, the thermal vibration of the sodium atom is strongly anisotropic, the vibration ellipsoid being a strongly prolate spheroid (Fig. 1a). The oxygen atoms are mildly anisotropic, except those bridging oxygens on mirror planes, which are fairly strongly anisotropic, the maximum vibration direction being normal to the Si-O-Si plane (Fig. 1c).

## Comparison with the tuhualite structure and the tuhualite structure type

Zektzerite is isostructural with tuhualite (Merlino,

a

b

c

Fig. 1. Zektzerite: stereoscopic views of the three structural components: (a) the Na-polyhedral chain; (b) the octahedral-tetrahedral chain, formed by alternating Li tetrahedra and Zr octahedra; and (c) the corrugated silicate double chain with six-tetrahedral repeat.
1969) and a synthetic orthorhombic phase $\mathrm{Na}_{2} \mathrm{Mg}_{2} \mathrm{Si}_{6} \mathrm{O}_{15}$ (Cradwick and Taylor, 1972). In tuhualite and in $\mathrm{Na}_{2} \mathrm{Mg}_{2} \mathrm{Si}_{6} \mathrm{O}_{15}$, the octahedral-tetrahedral chains consist of alternating $\mathrm{Fe}^{2+}$ tetrahedra and $\mathrm{Fe}^{3+}$ octahedra, and alternating Mg tetrahedra and Mg octahedra respectively. The angular distortion within the $\mathrm{Fe}^{2+}$ and $\mathrm{Mg}^{2+}$ tetrahedra respectively in these two structures are closely comparable to the angular distortion found within the Li tetrahedron in zektzerite. The coordination of Na [specifically $\mathrm{Na}(2)$ in $\mathrm{Na}_{2} \mathrm{Mg}_{2} \mathrm{Si}_{6} \mathrm{O}_{15}$ ] and the configuration of the silicate double chains are closely comparable in all three structures. In $\mathrm{Na}_{2} \mathrm{Mg}_{2} \mathrm{Si}_{6} \mathrm{O}_{15}$ there is an additional Na-position $[\mathrm{Na}(1): x=0.0000, y=0.4099, z=$ 0.2568 ], which is vacant in tuhualite and zektzerite. This Na site is nine-coordinated, with three short $\mathrm{Na}-\mathrm{O}$ bonds ranging from 2.50 to 2.63 A , and three pairs of long $\mathrm{Na}-\mathrm{O}$ bonds ranging from 2.75 to 3.06 A . The $\mathrm{NaO}_{9}$ polyhedron is a tri-capped trigonal prism, the three closer oxygens occurring at the centers of the prism faces. Because of the larger average cation-oxygen distance ( 2.81 A ), this site is more suitable for potassium. In tuhualite K would presumably prefer this site over Na . The crystal-chemical rela-
tionships among phases isostructural with tuhualite can be shown in terms of the cation sites:

$$
M(1) \quad M(2) \quad M(3) \quad M(4)
$$

Coordination number
$\mathrm{Na}_{2} \mathrm{Mg}_{2} \mathrm{Si}_{2} \mathrm{O}_{15}$

$$
\begin{equation*}
\mathrm{Na}^{+}(1) \mathrm{Na}^{+}(2) \mathrm{Mg}^{2+}(1) \mathrm{Mg}^{2+}( \tag{2}
\end{equation*}
$$

Tuhualite,

$$
\begin{array}{lll}
(\mathrm{Na}, \mathrm{~K}) \mathrm{Fe}^{2+} \mathrm{Fe}^{3+} \mathrm{Si}_{6} \mathrm{O}_{15} \\
.0 .5 \mathrm{H}_{2} \mathrm{O}^{3} & \square & \mathrm{Na}^{+}, \mathrm{K}^{+} \\
\mathrm{Fe}^{2+} & \mathrm{Fe}^{3+}
\end{array}
$$

## Zektzerite,

$\mathrm{LiNaZrSi} \mathrm{O}_{15} \quad \square \quad \mathrm{Na}^{+} \quad \mathrm{Li}^{+} \quad \mathrm{Zr}^{4+}$
where $\square$ indicates a vacancy.
It is clear that provided the coordination and total valence balance requirements are satisfied, a large number of combinations of different cations can produce the same structure type. Some possible examples of other compounds of the tuhualite structure type are:

[^3]

Fig. 2. A view of one-half of the zektzerite structure projected along [100]; the second half is obtained by reflection across a mirror plane (at $x=1 / 2$ ), passing through the oxygen atoms, $O(7), O(8)$, and $O(9)$, thereby doubling the silicate chain (cf. Fig. 1 in Merlino, 1969).

## Discussion

The Si-O bond lengths and the Si-O-Si angles in zektzerite

The average $\mathrm{Si}-\mathrm{O}$ bond lengths within $\mathrm{Si}(1), \mathrm{Si}(2)$, and $\operatorname{Si}(3)$ tetrahedra are $1.614,1.616$, and 1.610 A respectively. The variation of $\mathrm{Si}-\mathrm{O}$ bond lengths within each silicate tetrahedron reflects bond strengths received by the oxygen atoms from other cations, in addition to the contribution from silicon.
On the basis of the oxygen coordination the $\mathrm{Si}-\mathrm{O}$

[^4]bonds can be classified into three types: (A) oxygens bonded to one $\mathrm{Si}+\mathrm{Zr}+\mathrm{Li}$ (or Na ), (B) oxygens bonded to two Si only, (C) oxygens bonded to two Si +Na . The $\mathrm{Si}-\mathrm{O}$ bonds involving oxygens of (A), (B), and (C) types average $1.593( \pm 0.003) \mathrm{A}, 1.607( \pm$ $0.001) \mathrm{A}$, and $1.627( \pm 0.015) \mathrm{A}$ respectively.
The larger degree of variation of the $\mathrm{Si}-\mathrm{O}$ bond lengths involving oxygen atoms of the (C)-type can be further rationalized on the basis of the length of the $\mathrm{Na}-\mathrm{O}$ bond; when the $\mathrm{Na}-\mathrm{O}$ bond is longer, the $\mathrm{Si}-\mathrm{O}$ bond is shorter and vice versa. The shortest $\mathrm{Si}-$ O bond $[\mathrm{Si}(3)-\mathrm{O}(6), 1.590 \mathrm{~A}]$ involves the most charge-deficient oxygen atom [O(6), e.s.v. sum 1.77], a phenomenon first noted by Merlino (1969) in tuhualite.

The $\mathrm{Si}-\mathrm{O}-\mathrm{Si}$ bond angles fall into two groups: those involving oxygens lying on mirror planes average $155.7^{\circ}\left( \pm 4.2^{\circ}\right)$, whereas the other three within the single silicate chain average $147.6^{\circ}\left( \pm 0.6^{\circ}\right)$. These angles are all larger than the average $\mathrm{Si}-\mathrm{O}-\mathrm{Si}$ angle ( $140^{\circ}$ ) found by Liebau (1961) in a large number of silicates. The larger $\mathrm{Si}-\mathrm{O}-\mathrm{Si}$ angles are associ-
ated with shorter $\mathrm{Si}-\mathrm{O}$ bonds, in agreement with the molecular orbital calculations on silicate chain fragments (Tossell and Gibbs, 1977).

## Planarity of the corrugated single-silicate chain

The corrugated single-silicate chain has the sequence $\mathrm{O}(1)-\mathrm{Si}(1)-0(3)-\mathrm{Si}(2)-\mathrm{O}(5)-\mathrm{Si}(3)-\mathrm{O}\left(1^{\prime}\right)-$ $\mathrm{Si}\left(1^{\prime}\right)-\mathrm{O}\left(3^{\prime}\right)-\mathrm{Si}\left(2^{\prime}\right)-\mathrm{O}\left(5^{\prime}\right)-\mathrm{Si}\left(3^{\prime}\right)-$, the oxygen atoms being the bridging ones within the single-silicate chain (Fig. 1c). It is approximately planar, the plane being nearly parallel to the (100) plane. The minimum and maximum deviations of the bridging oxygen atoms from the least-squares plane defined by the silicon atoms only are 0.28 A and 0.45 A respectively. The degree of the corrugation of the chain is indicated by the ratio of the unit length of the corrugated chain $v s$. the chain length when fully stretched out, which is $10.16 \mathrm{~A} / 16.80 \mathrm{~A}=0.60$.

The planarity of the three crystallographically-distinct four-membered silicate rings

Within the double-silicate chains, three different rings can be discerned, which are:
(1) $\mathrm{Si}(1)-\mathrm{O}(7)-\mathrm{Si}\left(1^{\prime}\right)-\mathrm{O}(3)-\mathrm{Si}(2)-\mathrm{O}(8)-\mathrm{Si}\left(2^{\prime}\right)-\mathrm{O}\left(3^{\prime}\right)$
(2) $\mathrm{Si}(2)-\mathrm{O}(8)-\mathrm{Si}\left(2^{\prime}\right)-\mathrm{O}(5)-\mathrm{Si}(3)-\mathrm{O}(9)-\mathrm{Si}\left(3^{\prime}\right)-\mathrm{O}\left(5^{\prime}\right)$
(3) $\mathrm{Si}(1)-\mathrm{O}(7)-\mathrm{Si}\left(1^{\prime}\right)-\mathrm{O}(1)-\mathrm{Si}(3)-\mathrm{O}(9)-\mathrm{Si}\left(3^{\prime}\right)-\mathrm{O}\left(1^{\prime}\right)$

The average deviations of the bridging oxygen atoms from the least-squares planes passed through the silicon atoms only for rings (1), (2), and (3) are $0.17,0.23$, and 0.29 A respectively. The acute angles between the rings (1) and (2), (2) and (3), and (3) and (1) are $59.6^{\circ}, 52.8^{\circ}$, and $67.7^{\circ}$ respectively.

## Acknowledgments

It is a pleasure to thank Russell Boggs, Seattle, Washington for the zektzerite crystals, Professor George R. Rossman, California Institute of Technology for discussions on the crystal chemistry of
tuhualite, and Professor Charles T. Prewitt, State University of New York at Stony Brook, Dr. Ronald C. Rouse, University of Michigan, and Dr. Pete J. Dunn, Smithsonian Institution, Washington, D.C. for reviews of the paper. This research has been supported in part by the NSF grant EAR 76-13373 (Geochemistry).
