THE CRYSTAL STRUCTURE OF BURGESSITE, 
Co₂(H₂O)₄[AsO₃(OH)]₂(H₂O), AND ITS RELATION TO ERYTHRITRE

MARK A. COOPER AND FRANK C. HAWTHORNE

Department of Geological Sciences, University of Manitoba, Winnipeg, Manitoba R3T 2N2, Canada

ABSTRACT

The crystal structure of burgessite, ideally Co₂(H₂O)₄[AsO₃(OH)]₂(H₂O), a newly recognized supergene mineral from the Keeley mine, South Lorrain Township, Timiskaming District, Ontario, Canada, has been solved by direct methods and refined to an R index of 4.3% based on 494 observed reflections collected on a four-circle diffractometer with MoKα X-radiation. Burgessite is monoclinic, space group P2₁/n, a 4.7058(12), b 9.299(3), c 12.738(4) Å, β 98.933(8)°, V 550.6(5) Å³, Z = 2, Dₘes = 2.93 g/cm³. The structure consists of one unique As site that is [4]-coordinated by O atoms and occupied by As⁵⁺ with a <As–O> distance of 1.694 Å. There is one Co site occupied by Co and [6]-coordinated, with a <Co–O> distance of 2.096 Å. Bond-valence analysis of the final structure indicates three O atoms (O²⁻), one (OH) group and three (H₂O) groups in the asymmetric unit; note that the (OH) group is bonded to the As⁵⁺ cation, forming an acid arsenate group: AsO₃(OH). The resulting ideal formula is Co₂(H₂O)₄[As⁵⁺O₃(OH)]₂(H₂O), where the (H₂O) groups before the arsenate group are bonded to Co, and the (H₂O) group following the arsenate group is held in the structure solely by hydrogen bonds. A prominent motif in the burgessite structure is the [Co₂(H₂O)₄[As⁵⁺O₃(OH)]₂] chain, which extends in the [100] direction and occurs at the vertices of an orthorhombic net. These chains are linked into a three-dimensional structure by hydrogen bonds that involve (OH) bonded to As⁵⁺, (H₂O) bonded to Co, and (H₂O) held in the structure solely by hydrogen bonds. The crystal structure of erythrite is based on [Co₂(H₂O)₄(As⁵⁺O₄)₂] chains of the same bond-topology as that found in burgessite.

Keywords: burgessite, crystal structure, arsenate, erythrite.

SOUMAIRE

Nous avons résolu par méthodes directes la structure cristalline de la burgessite, de composition idéale Co₂(H₂O)₄[AsO₃(OH)]₂(H₂O), espèce minérale d’origine secondaire provenant de la mine Keeley, canton de South Lorrain, district de Timiskaming, Ontario, Canada, et nous l’avons affiné jusqu’à un résidu R de 4.3% en utilisant 494 réflexions observées et préllevées avec un diffractomètre à quatre cercles avec rayonnement MoKα. La burgessite est monoclinique, groupe spatial P2₁/n, a 4.7058(12), b 9.299(3), c 12.738(4) Å, β 98.933(8)°, V 550.6(5) Å³, Z = 2, Dₘes = 2.93 g/cm³. La structure contient un seul site As où loge As⁵⁺, entouré de quatre atomes d’oxygène à une distance <As–O> de 1.694 Å. Il y a un site Co où loge le Co à coordonnée [6], avec une distance <Co–O> de 2.096 Å. D’après une analyse des valences de liaison de la structure finale, il y a trois atomes d’oxygène (O²⁻), un groupe (OH) et trois groupes (H₂O) dans l’unité asymétrique, agencés autour du cation As⁵⁺ et formant ainsi un groupe arsenate acide: AsO₃(OH). Il en résulte la formule idéale Co₂(H₂O)₄[As⁵⁺O₃(OH)]₂(H₂O), dans laquelle les groupes (H₂O) inscrits devant le groupe arsenate sont liés au Co, et le groupe (H₂O) suivant le groupe arsenate n’est retenu dans la structure que par des liaisons hydrogène. Un motif prééminent dans la structure de la burgessite est la chaîne [Co₂(H₂O)₄[As⁵⁺O₃(OH)]₂] allongée dans la direction [100], située aux sommets d’un réseau orthorhombique. Ces chaînes sont rattachées à la structure tridimensionnelle par des liaisons hydrogène qui impliquent (OH) lié à As⁵⁺, (H₂O) lié au Co, et (H₂O) retenu dans la structure seulement par des liaisons hydrogène. La structure cristalline de l’erythrite est fondée sur des chaînes [Co₂(H₂O)₄(As⁵⁺O₄)₂] faisant preuve de la même topologie des liaisons que dans la burgessite.

Mots-clés: burgessite, structure cristalline, arsenate, erythrite.

Introduction

Burgessite, Co$_2$(H$_2$O)$_4$[AsO$_3$(OH)$_2$(H$_2$O)], was recently approved as a new mineral species (IMA 2007–055) by Sejkora et al. (2009). It occurs as a supergene phase at the Keeley mine, South Lorrain Township, Timiskaming District, Ontario, Canada. The Keeley mine was a significant producer of silver and cobalt from 1908 to 1942 and from 1963 to 1965. Mineralization is associated with the Nipissing diabase and calcite veins containing native silver, “smaltite”, nickeline, proustite and many other sulfide and sulfosalt minerals. Moreover, the primary mineralization has been affected by subsequent supergene alteration (Boyle & Dass 1971) leading to secondary oxysalts, including burgessite. Here, we report the structure of burgessite, and explore the relation of burgessite to erythrite.

Experimental Details

A crystal was attached to a glass fiber and mounted on a Bruker P4 diffractometer equipped with an Apex CCD detector and a MoKα X-radiation. In excess of a hemisphere of data (4012 reflections) was measured out to 45° 2θ [the crystal was quite small (Table 1), and no data were observed beyond a 2θ value of 45°] using a frame width of 0.1° and a frame time of 120 s. Unit-cell dimensions were determined from 682 reflections [with |F| > 7|F|], and are given in Table 1, together with other information pertaining to data collection and structure refinement. Of the 711 unique reflections, 494 reflections were considered as observed [|F| > 5|F|]. Absorption corrections were done using the program SADABS (Sheldrick 1998). The data were then corrected for Lorentz, polarization and background effects, averaged and reduced to structure factors.

All calculations were done with the SHELXTL PC (Plus) system of programs using neutral scattering factors; R indices are of the form given in Table 1 and are expressed as percentages. Systematic absences in the single-crystal X-ray-diffraction data are consistent with space group P2$_1$/n, and the structure was solved with this symmetry. The structure was solved by direct methods and refined by full-matrix least-squares on |F| to an R index of 4.3%. At the final stages of refinement, four H (hydrogen) sites were identified in difference-Fourier maps and were inserted into the refinement. The O (donor) – H distances were softly constrained to be close to 0.98 Å, e.g., Cooper & Hawthorne (1995), and the H–H distances were softly constrained to be close to 1.59 Å during refinement. The refined coordinates and displacement parameters of the atoms are listed in Table 2, selected interatomic distances and angles are given in Table 3, and bond valences (Brown & Altermatt 1985) are given in Table 4. A table of structure factors is available from the Depository of Unpublished Data on the MAC website [document Burgessite CM47_165].

* constrained to be equal during the refinement.
Coordination of cations

There is one As site completely occupied by As and coordinated by a tetrahedral arrangement of anions with a \(<\text{As}–\Phi\) distance (\(\Phi\) represents O, OH) of 1.694 Å, typical for tetrahedrally coordinated As\(^{5+}\). There is one Co site occupied dominantly by Co and coordinated by an octahedral arrangement of four O atoms and two (H\(_2\)O) groups. The chemical composition determined by electron-microprobe analysis (Sejkora \textit{et al.} 2009) indicates a mean Co-site composition of Co\(_{0.875}\)Ni\(_{0.125}\). Summing the constituent cation and anion radii (Shannon 1976) gives a prediction for the \(<\text{Co}–\text{O}\) distance of 2.095 Å, in close agreement with the observed value of 2.096 Å (Table 3).

Anion identities and hydrogen bonding

There are seven crystallographically distinct anions, O(1)–O(7). Inspection of the bond-valence table (Table 4) shows that O(4) is an (OH) group and that O(5), O(6) and O(7) are (H\(_2\)O) groups, in accord with the stereochemistry of the H atoms located at the final stages of refinement. In addition to being an (OH) group, O(4) also bonds to As\(^{5+}\), forming an acid arsenate group: (AsO\(_3\)OH). The O(7) site is disordered off the center...
of symmetry at \((\frac{1}{2} 0 \frac{1}{2})\) and is half-occupied, with an \(\text{O}(7)–\text{O}(7)\) distance of 2.07(4) Å. Details of the hydrogen bonds are given in Table 3 and are described below. The \(\text{H}(1)\) atom forms a hydrogen bond to \(\text{O}(4)\), the acid anion of the arsenate group (Table 4), \(\text{H}(4)\) forms a hydrogen bond to \(\text{O}(1)\), which also accepts a hydrogen bond from \(\text{H}(2)\), and \(\text{H}(3)\) forms a hydrogen bond to \(\text{O}(3)\). Three additional \(\text{H}\) sites could not be found, but the bond valence incident at \(\text{O}(4)\) and \(\text{O}(7)\) indicates that these anions must be \((\text{OH})\) and \((\text{H}_2\text{O})\), respectively; these \(\text{H}\) atoms are labeled \(\text{H}(5)\), \(\text{H}(6)\) and \(\text{H}(7)\) in Table 4. From the local stereochemistry and the bond valence incident at adjacent anions, it is apparent that the \(\text{H}\) atom attached to \(\text{O}(4)\) forms a hydrogen bond with \(\text{O}(7)\), and the \(\text{H}\) atoms of the \((\text{H}_2\text{O})\) group at \(\text{O}(7)\) form a hydrogen bond to \(\text{O}(3)\) and a bifurcated hydrogen bond to \(\text{O}(5)\) and \(\text{O}(6)\).

**Bond topology**

Pairs of adjacent \(\text{CoF}_6\) octahedra (\(\Phi\) represents an unspecified anion) share an edge to form a \([\text{Co}_2\Phi_{[10]}]\) dimer, and \(\text{AsF}_4\) tetrahedra link pairs of vertices in the adjacent octahedra to form a compact \([\text{Co}_2(\text{AsF}_4)_{\Phi_{[6]}}]\) cluster (Fig. 1a). This cluster is one of four predicted by Hawthorne (1983) to be the most stable of the (twenty-eight completely connected) graphical and geometrical isomers of the form \([6][\text{M}_2(\text{TF}_4)\Phi_{n}]\). In burgessite, these clusters polymerize in the \(a\) direction through linkage of tetrahedron vertices to the shared edge of two octahedra of each adjacent cluster to form a chain of the form \([\text{Co}_{2}(\text{H}_2\text{O})_{4}\text{As}^{5+}\text{O}_3(\text{OH})_{2}]\) (Figs. 1b, c). These chains extend in the [100] direction and occur at the vertices of an orthorhombic net (Fig. 2). They are linked into a three-dimensional structure by hydrogen bonds that involve \((\text{OH})\) bonded to \(\text{As}^{5+}\), \((\text{H}_2\text{O})\) bonded to \(\text{Co}\), and \((\text{H}_2\text{O})\) held in the structure solely by hydrogen bonds.

**Related structures**

Burgessite is not isostructural with any other mineral or inorganic compound; however, it is chemically similar to erythrite \(\text{Co}_3(\text{AsO}_4)_{2}(\text{H}_2\text{O})_8\) (Wildner et al. 1996, Capitelli et al. 2007). Both erythrite and burgessite contain chains of the form \([\text{Co}_2(\text{H}_2\text{O})_{4}(\text{AsF}_4)_{\Phi_{12}}]\); these differ only in the composition of the oxygen of the \((\text{AsF}_4)\) group that does not share a vertex with a \(\text{Co}\) octahedron of the \([\text{Co}_2(\text{H}_2\text{O})_{4}(\text{AsF}_4)_{\Phi_{12}}]\) chain: \(\text{O}\) in erythrite (Fig. 3a), and \((\text{OH})\) in burgessite (Fig. 3b). The \([\text{Co}_2(\text{H}_2\text{O})_{4}(\text{AsF}_4)_{\Phi_{12}}]\) chains are parallel to [001] in erythrite and [100] in burgessite, and the corresponding unit-cell translations in these directions are 4.76 and 4.71 Å, respectively (Wildner et al. 1996, Table 1). In erythrite, the \([\text{Co}_2(\text{H}_2\text{O})_{4}(\text{AsO}_4)_{2}]\) chains are connected at the outward-projecting vertices of the \((\text{AsO}_4)\) groups, which share corners with the \((\text{Co}_2\Phi_{[6]}\text{O}_2)\) octahedra (Fig. 4a), forming a [010] sheet of composition \([\text{Co}_3(\text{H}_2\text{O})_8(\text{AsO}_4)_{2}]\). These sheets are linked into a three-dimensional structure by hydrogen bonding in the [010] direction.

---

**Fig. 1.** Polyhedron linkages in the crystal structure of burgessite. (a) The \([\text{Co}_2(\text{H}_2\text{O})_{4}\text{As}^{5+}\text{O}_3(\text{OH})_{2}]\) cluster. Shown in (b), (c) are oblique views of the \([\text{Co}_2(\text{H}_2\text{O})_{4}(\text{As}^{5+}\text{O}_3(\text{OH})_{2}]\) chain. Convention: \((\text{AsF}_4)\) tetrahedra: dark grey, \((\text{CoF}_6)\) octahedra: pale grey, \((\text{OH})\) group: dark grey circle, and \(\text{H}\) atoms: black circles. The \(\text{O}_{\text{donor}}–\text{H}\) bonds are shown as solid black lines.
A conceptual transformation of erythrite to burgessite is shown in Figures 4 and 5. Hydroxylation of the \((\text{AsO}_4)\) group in erythrite is accompanied by loss of interchain \(\text{Co(H}_2\text{O})_3\) components (Figs. 4b, 5b). The transformation begins with an “attack” on the Co–O–As link between the \([\text{Co}_2(\text{H}_2\text{O})_3(\text{AsO}_4)_2]\) chains and the intervening \([\text{Co(H}_2\text{O})_3\text{O}_2]\) octahedra (Figs. 4a, 5a), giving rise to \([\text{AsO}_3(\text{OH})]\) groups, and a net loss of interchain \(\text{Co(H}_2\text{O})_3\), with retention of one (H\(_2\)O) group (Figs. 4b, 5b). The net chemical reaction is: erythrite + 2 H\(^+\) → burgessite + \(\text{Co(H}_2\text{O})_3\). This exchange is accompanied by coupled rotation and lateral offset of neighboring \([\text{Co}_2(\text{H}_2\text{O})_3(\text{AsO}_4)_2]\) chains (Figs. 4b, 5b). In addition to the lateral shift in chains shown in Figure 5b (i.e., relative to \([001]\) in erythrite), there is an additional offset between neighboring chains that is perpendicular to the first shift, \(\text{cf.}\) the \(\beta\) angles in erythrite (Fig. 5a) and burgessite (Fig. 5c). Finally, the interstitial (H\(_2\)O) group in burgessite assumes one of two equally likely positions equidistant from the neighboring (OH) groups that are involved in mutual hydrogen-bonding (Figs. 4c, 5c). The net geometrical change associated with the erythrite → burgessite transformation is a 13% reduction in cell volume, resulting from contraction of the interchain region.

**Connectivity details in erythrite and burgessite**

A comparison of the erythrite and burgessite structures reveals key differences in the linkage between the \([\text{Co}_2(\text{H}_2\text{O})_3(\text{AsO}_4)_2]\) chains, in particular the anion of the \((\text{AsO}_4)\) group that projects outward from the \([\text{Co}_2(\text{H}_2\text{O})_3(\text{AsO}_4)_2]\) chain. In erythrite, bond-valence requirements of this O(1) anion are satisfied by (1) a strong bond (0.40 \(\text{vu}\)) from the interchain Co(1) atom, and (2) two hydrogen bonds (0.20 \(\text{vu}\) each) from the H(1) atoms of two (H\(_2\)O) groups [O(4)] from an adjacent interchain Co(1) octahedron (Table 5, Figs. 4a, 5a). In burgessite, the bond-valence requirements of the O(4) anion are satisfied by (1) an attached H(7) atom (0.80 \(\text{vu}\)), and (2) a hydrogen bond (0.20 \(\text{vu}\)) from the H(1) atom of an (H\(_2\)O) group [O(5)] from an adjacent chain (Table 4, Fig. 4c). In both structures, (H\(_2\)O) groups along the outer margins of the chain hydrogen-bond to shared octahedron–tetrahedron vertices within the chain (Fig. 3, Tables 4, 5). The O(2) anions near the
central axis of the chains bond to one As and two Co
cations, and their bond-valence requirements are satis-
fied in the same way in both structures (Fig. 3, Tables
4, 5). In erythrite, the O(3) anion receives an intrachain
hydrogen bond from H(2) (Fig. 3b), O(1) also receives a hydrogen bond from H(4) belonging to
an (H₂O) group from a neighboring chain (Fig. 4c). In addition to the intrachain hydrogen bond from H(3)
(Fig. 3b), O(3) also receives a hydrogen bond from the half-occupied H(6) that belongs to the interstitial (H₂O)
group at O(7) (Fig. 4c).

The As–O(3) bond in burgessite is somewhat shorter
than the As–O(3) bond in erythrite; this shortening
occurs in response to a local bond-valence deficiency
at O(3), where the neighboring interstitial (H₂O) group
is absent (Fig. 4c). The (H₂O) group at O(5) belongs
to the [Co₂(H₂O)₄(AsF₄)₂] chain in erythrite and does
not receive any hydrogen bonds (Table 5), whereas its
counterpart [O(5),O(6)] in burgessite receives a weak
bifurcated hydrogen-bond from H(5) of the interstitial
(O(7) (H₂O) group (50% of the time) (Fig. 4c).

Hydrogen bonds are directed outward from the
[Co₂(H₂O)₄(AsF₄)₂] chains from the flanking (H₂O)
groups in a different manner in erythrite and burges-
site. In erythrite, H(4) forms a hydrogen bond to the
O(4) (H₂O) group of the interchain
Co(1) octahedron (Fig. 4a). In burgessite, the analogous
anions are O(1) and O(3). In addition to the intrachain hydrogen bond from H(2) (Fig. 3b), O(1)

![Fig. 3. The [Co₂(H₂O)₄(AsF₄)₂] chains in (a) erythrite projected onto (100), and (b) burgessite
projected down an axis 14% from [010]. Legend as in Figures 1 and 2.](image)

Legend as in Figures 1, 2, and 4, with black straight arrow showing chain translation, and the grey to black shaded curved arrow showing the relative rotation of the chains.
additional hydrogen-bond from the H(7) proton of the
(OH) group at O(4) to the (H2O) group occupying one
(of two possible) adjacent O(7) sites (Fig. 4c). We noted
above that the H atoms associated with the (OH) group
and the interstitial (H2O) group could not be located in
the difference-Fourier map; this can be attributed to the
positional disorder that must occur at these H positions
in relation to the disorder present at the O(7) position.

Burgessite and erythrite occur together at the Keeley
mine and are very similar in appearance, but are easily
distinguished by their powder-diffraction patterns. Their
close paragenetic and structural association leads us to
suggest that careful inspection of “erythrite” samples
from this and other localities will likely lead to further
discoveries of burgessite.

ACKNOWLEDGEMENTS

We thank Herta Effenberger and Stuart Mills for
their reviews of this paper, and Associate Editor Peter
Leverett and Editor Bob Martin for their expeditious
handling of the manuscript. This work was supported
by a Canada Research Chair in Crystallography and
Mineralogy and by Discovery, Equipment and Major
Installation grants from the Natural Sciences and Engi-
neering Research Council of Canada to FCH, and by
Innovation grants to FCH from the Canada Foundation
for Innovation.
