ABSTRACT

Paulscherrerite, UO3(OH)2, occurs as an abundant dehydration product of metaschoepite at the Number 2 Workings at Radium Ridge, Northern Flinders Ranges, South Australia. The mineral name honors the contribution of Swiss physicist Paul Scherrer (1890–1969) to mineralogy and nuclear physics. Individual paulscherrerite crystals are tabular, reaching a maximum of 500 nm in length. Paulscherrerite has a canary yellow color and displays no fluorescence under UV light. Chemically, paulscherrerite is a pure uranyl hydroxide/hydrate, containing only traces of other metals (<1 wt% in total). Bulk (mg) samples always contain admixtures of metaschoepite (purest samples have ~80 wt% paulscherrerite). A thermogravimetric analysis corrected for the presence of metaschoepite contamination leads to the empirical formula UO3·1.02H2O, and the simplified structural formula UO2(OH)2.

Powder diffraction shows that the crystal structure of paulscherrerite is closely related to that of synthetic orthorhombic α-UO2(OH)2. However, splitting of some X-ray diffraction lines suggests a monoclinic symmetry for type paulscherrerite, with a = 4.288(2), b = 10.270(6), c = 6.885(5) Å, β = 90.39(4)°, V = 303.2(2) Å3, Z = 4, and possible space groups P21/m, P21/m, or P2/m.

Paulscherrerite-like material was synthesized using various methods, including heating metaschoepite in water at 150 °C and slow hydration of UO3(am) in air; material synthesized using hydrothermal techniques displayed peak splitting indicative of monoclinic symmetry. Paulscherrerite has been reported under the name “dehydrated schoepite” as an early weathering product of uraninite/pitchblende in several deposits, such as Shinkolobwe, Zaire; Nopal I deposit, Mexico; and the granitic pegmatites of New Hampshire, U.S.A.

Keywords: Paulscherrerite, new mineral, uranyl hydroxide, “dehydrated schoepite,” powder diffraction, Number 2 Workings, Radium Ridge, Northern Flinders Ranges, South Australia

INTRODUCTION

Hydrated uranyl oxy-hydroxides and aims of this paper

More than 170 minerals containing hexavalent uranium (uranyl) are known (Burns 1999), including four closely related uranyl oxide hydrates/hydroxides without interlayer cations that form the schoepite subgroup of the fourmarierite group (Burns 1999): schoepite, metaschoepite, paraschoepite, and “dehydrated schoepite” (Table 1). The empirical chemical formula for these minerals is UO3⋅xH2O (x = 0.8–2.25), but the nature of the natural uranyl oxide hydrates/hydroxides has been a subject of controversy since the description of schoepite by Walker (1923). Christ and Clark (1960) published the first review providing chemical, single-crystal diffraction and optical data for schoepite, metaschoepite, and paraschoepite from Shinkolobwe, Katanga district, Democratic Republic of Congo. Christ and Clark (1960) also analyzed an orthorhombic “dehydrated schoepite,” with the nominal chemical formula UO3·H2O. They demonstrated that this product formed by dehydration of schoepite under mechanical pressure or when schoepite is placed over concentrated H2SO4, but suggested that in nature schoepite dehydrated to metaschoepite (their schoepite II), which appears stable. In the past decade, detailed X-ray powder diffraction (Finch et al. 1997) and single-crystal studies have provided us with a clearer understanding of the nature of these minerals (Table 1), culminating with refinements of the crystal structures of schoepite and metaschoepite (Finch et al. 1996, 1998; Weller et al. 2000). Schoep and Stradiot (1947) described paraschoepite, 5UO3·9½H2O, but provided few data. Paraschoepite was reported by Christ and Clark (1960) in a sample mixture consisting of schoepite and “dehydrated schoepite.” Finch et al. (1998) failed to identify any paraschoepite in the many samples they examined, and concluded that the sample described by Christ and Clark (1960) as paraschoepite was almost certainly a mixture of metaschoepite, “dehydrated schoepite,” and ianthinite.

“Dehydrated schoepite” is the only member of the schoepite subgroup that has not been formally described as a mineral species, despite being a well-established and well-defined phase (e.g., Finch et al. 1998). Here we present a formal description of the mineral paulscherrerite, formerly referred to as “dehydrated schoepite.” This description is based on a new occurrence from the Number 2 Workings on Radium Ridge, near Arkaroola,
Northern Flinders Ranges, South Australia. We also provide evidence for a pseudo-orthorhombic (monoclinic) symmetry for natural “dehydrated schoepite,” compared with the orthorhombic symmetry reported for the synthetic, stoichiometric α-UO₂(OH)₂ crystals analyzed using single-crystal methods by Taylor (1971) and Taylor and Hurst (1971).

**Significance of the “schoepite” subgroup**

Schoepite, metaschoepite, and paulscherrerite are important secondary U(VI) phases resulting from the weathering of uranium minerals such as uraninite as well as the corrosion of anthropogenic uranium-bearing solids (Finch and Ewing 1992). Whereas rutherfordite is an important U(VI)-mineral in carbonate-rich groundwater, the oxy-hydroxides of the schoepite subgroup are observed in acidic to near-neutral pH systems (e.g., Brugger et al. 2003b). The latter commonly act as precursors in the formation of more complex and stable assemblages of secondary phases, including metal-uranyl-hydrates such as bocquerelite, Ca(UO₂)₆(OH)₆·8H₂O, and compregnacite, K₃(UO₂)₆O₆(OH)₆·8H₂O (Sowder et al. 1996; Sandino and Grambow 1994), and uranyl silicates and phosphates (Finch and Ewing 1992). Schoepite and metaschoepite may also form as hydrolysis products of natural uranyl- and alkaline metal sulfates (e.g., natrozippeite or zippeite, (Na,K)₄(UO₂)₆[(OH)₁₀ as hydrolysis products of natural uranyl- and alkaline metal carbonates (Finch and Elburg 2006). At the Number 2 Workings, secondary U minerals are overprinted by the epithermal mineralization. Geochemically, the Number 2 Workings bear some similarities with the 440 Myr old diopside-titanite veins deposited at 510 ± 20 °C and located ~3 km South of Number 2 Workings (Bakker and Ewing 2006). At the Number 2 Workings, secondary U minerals occur in the cavities of the epithermal quartz and as replacement of the primary U-bearing mineral, and include metaschoepite, weeksite, beta-uranophane, metatorbernite, soddyite, kasolite, billietite, Ce-rich francisite (type locality; Meissner et al. 2010), Ba-bearing boltwoodite, spriggite (type locality; Brugger et al. 2004), curite, and barite (Brugger et al. 2003a).

**PAULSCHERRERITE, A NEW MINERAL**

**Occurrence**

The type locality for paulscherrerite is the Number 2 Workings, Radium Ridge near Mount Painter, near Arkaroola, Northern Flinders Ranges, South Australia (Australian Grid coordinates: 54J 0339200 m E, 6655430 m N). The occurrence is hosted by the Mesoproterozoic Mount Painter Inlier, which contains large volumes of granites and gneisses highly enriched in U and Th (several tens of parts per million). The radiogenic heat released by these granites was responsible for a long-lasting thermal anomaly (Sandiford et al. 1998; Neumann et al. 2000; Elburg et al. 2003). Together with Paleozoic intrusions of granitic and pegmatitic melts, this resulted in long-standing, large-scale hydrothermal activity within and around the Mount Painter area, which continues to this day as evidenced by active hot springs (Brugger et al. 2005). The province contains many small hematite-U + Cu-Nb-REE deposits, and a large U-rich epithermal system characterized by complex quartz ± fluorite veins and breccias (Mount Gee-Mount Painter system).

Radium Ridge (including Number 2 Workings) was exploited intermittently for radium between 1906 and 1934 (Coats and Blissett 1971; Brugger et al. 2003a). The Number 2 Workings are located on a lens of coarse-grained hematite ± quartz, containing locally abundant monazite-(Ce), xenotime-(Y), fluorapatite, and a Ca-Fe-phosphate. Accessory minerals include a metamict, strongly heterogeneous samarskite-group mineral with present-day composition plotting in the ishikawaite [(U,Y,Fe)NbO₄] and Fe-rich samarskite-(Y) [(Y,Fe,U)NbO₄] fields (Hanson et al. 1999), and an unknown primary U-Pb(±Mn)-bearing mineral. This high-temperature Fe-U-Nb-BREE mineralization is located at the base of the Mount Gee epithermal system, and is overprinted by the epithermal mineralization. Geochemically, the Number 2 Workings bear some similarities with the 440 Myr old diopside-titanite veins deposited at 510 ± 20 °C and located ~3 km South of Number 2 Workings (Bakker and Ewing 2006). At the Number 2 Workings, secondary U minerals occur in the cavities of the epithermal quartz and as replacement of the primary U-bearing mineral, and include metaschoepite, weeksite, beta-uranophane, metatorbernite, soddyite, kasolite, billietite, Ce-rich francisite (type locality; Meissner et al. 2010), Ba-bearing boltwoodite, spriggite (type locality; Brugger et al. 2004), curite, and barite (Brugger et al. 2003a).

Notes: For comparison purposes, the unit cells settings are chosen so that the b-axis is perpendicular to the structural sheets, except for γ-UO₂(OH)₂, where the unique axis b is parallel to the structural sheets. A bold font emphasizes the axis perpendicular to the structural sheets.
The name honors the contribution of the Swiss physicist Paul Scherrer (1890–1969) to mineralogy and nuclear physics. Scherrer was appointed at the ETH Zürich in 1920 together with Dutch physicist Peter Debye (1936 Nobel Prize in chemistry), and became head of the Physics Institute in 1927. The collaboration between Scherrer and Debye resulted in the development of the powder diffraction theory (e.g., the Scherrer equation), and the design of the Debye-Scherrer X-ray powder diffraction camera, which both had a strong impact on mineralogical sciences. After the initial years of successful research activities in the field of X-ray scattering in crystals, liquids, and gases, Scherrer increasingly turned his attention to nuclear physics. In 1946 he was appointed to the Presidency of the Swiss Study Commission for Atomic Energy, and nuclear and reactor physics developed thanks to his initiative. Scherrer was also instrumental in dissuading the Swiss government from pursuing its own military nuclear program. The name paulscherrerite is chosen in preference to Schoepite.

Together with weeksite, metaschoepite, Fe-Mn-oxy hydroxides, and occasionally spriggite, paulscherrerite is the main mineral replacing the unknown primary U-Pb-(Mn?)-bearing mineral at the Number 2 Workings (Fig. 2a). Paulscherrerite also commonly forms pseudomorphs after platy crystals of metaschoepite in cavities of the late epithermal quartz (Fig. 2b).

**Figure 1.** Geometry of the uranyl layers in schoepite, metaschoepite, and $\alpha$-UO$_2$(OH)$_2$. Spheres represent uranium atoms, rods are U-O bonds. The darker spheres represent U1,U2,U5,U6 and U2,U3 in schoepite (Finch et al. 1996) and metaschoepite (Weller et al. 2000), respectively, while the lighter ones represent U3,U4,U7,U8 and U1,U4. The shaded areas are occupied by one oxygen atom in the case of schoepite and metaschoepite, but by two O atoms in $\alpha$-UO$_2$(OH)$_2$, causing the main topological difference between the uranyl sheets and the change in uranyl coordination from a pentagonal bipyramid in schoepite/metaschoepite to an hexagonal bipyramid in $\alpha$-UO$_2$(OH)$_2$.

Field of view 2 cm. (b) Paulscherrerite replacing elongated platy crystals of metaschoepite associated with $\beta$-uranophane in cavities in late, epithermal smoky quartz. Image width: 15 mm. Sample MGL 92689.

**Name, type material, and classification**

The name honors the contribution of the Swiss physicist Paul Scherrer (1890–1969) to mineralogy and nuclear physics. Scherrer was appointed at the ETH Zürich in 1920 together with Dutch physicist Peter Debye (1936 Nobel Prize in chemistry), and became head of the Physics Institute in 1927. The collaboration between Scherrer and Debye resulted in the development of the powder diffraction theory (e.g., the Scherrer equation), and the design of the Debye-Scherrer X-ray powder diffraction camera, which both had a strong impact on mineralogical sciences. After the initial years of successful research activities in the field of X-ray scattering in crystals, liquids, and gases, Scherrer increasingly turned his attention to nuclear physics. In 1946 he was appointed to the Presidency of the Swiss Study Commission for Atomic Energy, and nuclear and reactor physics developed thanks to his initiative. Scherrer was also instrumental in dissuading the Swiss government from pursuing its own military nuclear program. The name paulscherrerite is chosen in preference...
of scherreriite because of phonetic confusion with the mineral schairerite, Na21(SO4)7ClF6. The mineral and its name have been approved by the Commission on New Minerals, Nomenclature and Classification of the International Mineralogical Association (2008-022). Holotype material (G31382) is deposited in the South Australian Museum, North Terrace, 5000 Adelaide, Australia, and cotype material (MGL 79287) in the Musée Géologique, UNIL-Anthropole, 1015 Lausanne, Switzerland.

In the classification of Strunz and Nickel (2001), paulscherrerite belongs to group 4.GA.20: uranyl hydroxides without additional cation.

**Appearance and physical properties**

Paulscherrerite occurs most commonly as a microcrystalline powdery product (Fig. 2a) forming part of the mineral assemblage resulting from the weathering of an unknown U-Pb-(Mn?)-bearing mineral. Paulscherrerite commonly replaces metaschoepite, which occurs either in a massive form (Fig. 2b) or as acicular to blocky crystals up to 1 mm in length (Fig. 3a). Paulscherrerite pseudomorphs after metaschoepite crystals display porous surfaces (Fig. 3b) when examined by scanning electron microscopy. The paulscherrerite crystallites reach a maximum length of ~500 nm (Fig. 3c). They are aligned along a crystallographic axis of the replaced metaschoepite. Paulscherrerite crystals show a tabular morphology, with at least one prominent monoclinic prism (Fig. 3c).

Paulscherrerite is canary yellow, with a streak of similar color. It shows no fluorescence under UV-light. The Mohs hardness could not be measured on the powdery material available, and neither cleavage nor fracture was observed. The calculated density is 6.66 g/cm³ for the ideal formula UO₂(OH)₂. Because the mineral occurs in powdery form and is always finely mixed with metaschoepite (10 samples analyzed by XRD), no density measurement using the pycnometer method was undertaken.

No optical properties are reported because the mineral occurs as a powdery replacement product (grain size ≤ 500 nm; Fig. 3c), unsuitable for optical measurements. The average refractive index calculated using the Gladstone-Dale relationship with the constants reported by Mandarino (1981) is n (calc.) = 1.874 for the ideal composition UO₂(OH)₂. This value is close to the average value (1.862) measured on synthetic α-UO₂(OH)₂ by Harris and Taylor (1962).

**X-ray crystallography**

In the absence of a suitable crystal, no single-crystal study could be carried out, and the identification of the nature of paulscherrerite relies mainly on its characteristic powder X-ray diffraction pattern (Fig. 4; Table 2; see also Finch et al. 1997). X-ray powder-diffraction data were collected using a Huber Guinier Image Plate G670 camera (South Australian Museum) with CoKα₁ X-radiation (1.78892 Å). NIST SRM 640a silicon power was used as internal standard. Ten samples from different hand specimens were screened using a 100 mm diameter Guinier-Hägg camera (South Australian Museum) under a weak vacuum, with photographic film as a detector and CrKα₁ X-radiation (2.2897 Å). The necessary sample quantity for the latter camera was ~1 mg, while more than 10 mg were necessary to obtain good patterns using the G670 camera. After development, the film was digitized using an optical scanner, the diffractogram was extracted using NIH image (developed at the U.S. National Institute of Health and available at http://rsb.info.nih.gov/nih-image/), and the 2θ scale was calibrated by a linear regression based on the three most intense Si lines.

The measured intensities and peak positions for the holotype are reported in Table 2. Peak positions and intensities were extracted from a full profile fit using the *fit2k* software (http://www.unipress.waw.pl/fit2k/). The fit included a baseline sub-

![Figure 3. Scanning electron microscope (SEM) images of metaschoepite crystals from the Number 2 Workings, Radium Ridge, South Australia, replaced by paulscherrerite. Rietveld refinement was conducted using the Rietica package (Hunter 1998). The pattern was modeled using a mixture of α-UO₂(OH)₂ (Taylor 1971; Taylor and Hurst 1971; space group Cmca) and metaschoepite (Weller et al. 2000). The fit (Fig. 4) shows that paulscherrerite is associated with significant amounts of metaschoepite (~30% metaschoepite, ~70% paulscherrerite); the refined orthorhombic cell for paulscherrerite has \( a = 4.2876(2) \) Å, \( b = 10.2569(3) \) Å, \( c = 6.8919(3) \) Å, \( V = 303.09(2) \) Å³. The unit cell for the associated metaschoepite is listed in Table 3.

The Rietveld refinement has relatively high residuals (\( R = 8.5\% \)). Close inspection shows that a few reflections appear to be doublets (inset in Fig. 4), and by excluding the doublets from the Rietveld fit the \( R \) value reduced to 4.5%. This relatively high-residual value is mainly related to difficulties in modeling peak shape. The observed peak splitting suggests that the orthorhombic structure reported for synthetic α-UO₂(OH)₂ and that of paulscherrerite differ by a small distortion, which implies monoclinic symmetry for paulscherrerite. We tested this hypothesis by using a Le Bail fit (Le Bail et al. 1988), which showed that when the \( \beta \) angle deviated slightly from 90.0° it was possible to index the experimental pattern with good accuracy (final \( R = 4.9\% \); inset in Fig. 4; Table 2).

Hence paulscherrerite is monoclinic (pseudo-orthorhombic), with \( a = 4.288(2) \), \( b = 10.270(6) \), \( c = 6.885(5) \) Å, \( \beta = 90.39(4)° \), \( V = 303.2(2) \) Å³, and \( Z = 4 \). The \( a:b:c \) ratio calculated from these unit-cell parameters is 0.4175:1:0.6704. The following space groups explain all 46 reflections listed in Table 2 [tolerance 0.15 \( 2\theta \); program Checkcell (Checkcell: part of the MGP-Suite Suite of programs for the interpretation of X-ray experiments, by Jean Laugier and Bernard Bochu, ENSP/Laboratoire des Matériaux et du Génie Physique, BP 46, 38042 Saint Martin d’Hères, France. http://www.inpg.fr/LMGp and http://www.ccp14.ac.uk/tutorial/lmgp/)], \( P2_1/m, P2_1, P2_1/m \) and \( P2_1/m, P2_1/a \) also explains all reflections, but is discarded on the ground that the \( a \) glide is not a subset of the parent structure, orthorhombic α-UO₂(OH)₂.

Laser Raman spectra were recorded in the range from 4000 to 100 cm⁻¹ with a Renishaw Ramascope 1000 (University of South Australia) using an argon laser (488 nm line) and excitation through a Leica DMLM optical microscope (Si standard, spectral resolution 2 cm⁻¹, unpolarized laser light, random sample orientation). Due to the small excitation volume of Raman (a few cubic micrometers) and the combination with optical microscopy (paulscherrerite and metaschoepite have different yellow tinges), it was possible to record nearly pure spectra for paulscherrerite. The Raman spectra (Fig. 5a) are dominated by a broad band related to \( \nu(OH) \) (~3245–3435 cm⁻¹, with maxima at ~3290 and 3340 cm⁻¹) and an intense band attributed to \( \nu_1(UO_2^{2+}) \) centered at 840 cm⁻¹. Weak bands at low wavenumbers (360, 460, 505, and 557 cm⁻¹) are attributed to stretching modes of \( \nu(UO) \) for the planar O atoms (as opposed to axial O atoms in the uranyl group, \( UO_2^{2+} \)), based on the interpretation of the IR spectrum.
The empirical formula, using the total water content measured by TGA (see below), based on 1 U atom per formula unit (pfu) and assuming that all U atoms are present as uranyl, is UO$_3$⋅H$_2$O on material mounted in epoxy resin and hand-polished using a water-diamond suspension (final polish using 1 μm diamond). Electron microprobe analyses show that paulscherrerite is an almost pure uranyl oxide-hydrate, with <1 wt% of minor elements such as rare earth elements, Al, Ba, and Pb (Table 4). The presence of H$_2$O was confirmed by infrared and Raman spectroscopy, and quantified using thermogravimetric analysis (TGA; Ecole Polytechnique Fédérale, Lausanne).

SYNTHESIS OF PAULSCHERRERITE-LIKE MATERIAL:
“DEHYDRATED SCHOEPITE”

The empirical phase relationships among schoepite, metaschoepite, and “dehydrated schoepite” were summarized by Finch et al. (1998), and an updated representation of their conclusions is shown in Figure 8. As pointed out by Hoekstra and Siegel (1973), stoichiometric α-UO3(OH)2 so far has only been synthesized via cooling of β-UO3(OH)2, (Hoekstra and Siegel 1973). Paulscherrerite synthesis (US3)††

groups and hydroxyl anions. Protas (1959) and Čejka (1999; p. 583) provide data for metaschoepite. Upon heating, metaschoepite [(UO3)2O6(OH)12]·10H2O loses 10 H2O between 60 and 125 °C (molecular water), and 6 H2O corresponding to 12 hydroxyl groups between 135 and 450 °C. The TGA curves of metaschoepite are similar to those of synthetic UO3·2H2O, and show endotherms at 130 and 300 °C (dehydration and dehydroxylation), at 630 and 700 °C (transition of α-UO3 to U3O8), and an exotherm at 480 °C corresponding to α-UO3 crystallization from amorphous UO3.

To assess the reliability of our TGA, we measured a synthetic metaschoepite. Two X-ray diffraction peaks at 3.222(2) and 3.593(2) Å cannot be explained by the crystal structure of Weller et al. (2000). This α-UO3(OH)2; crystal measured by Taylor (1971) was probably synthesized via cooling of β-UO3(OH)2, (Hoekstra and Siegel 1973). Prepared by standing UO3(am) in air for 24 months. After 8 months poorly crystalline α-UO3(OH)2 was obtained. The unit cell reported here is for material after 24 months, which had sharp diffraction peaks and consisted of 18.0(7) mol% metaschoepite and 82.0(7) mol% α-UO3(OH)2 (from Rietveld analysis). Synthesized by placing synthetic metaschoepite (see US3) at 150 °C in water for 11 days. Commercial yellow UO3(am) manufactured by COGEMA and purchased from LOBOSI PROLABO, Paris, France, in 1981. It now consists of 56.(5) mol% metaschoepite and 43.6(7) mol% α-UO3(OH)2, (from Rietveld analysis). The empirical phase relationships among schoepite, metaschoepite, and “dehydrated schoepite” were summarized by Finch et al. (1998), and an updated representation of their conclusions is shown in Figure 8. As pointed out by Hoekstra and Siegel (1973), stoichiometric α-UO3(OH)2 so far has only been synthesized via cooling of β-UO3(OH)2, and the only single-crystal data available are for this material. Unfortunately the details of the synthesis of the crystal used by Taylor (1971) are not reported, but were part of a 1958 patent application (Harris and Taylor 1962). The products synthesized via other routes appear to be water-deficient, with water contents corresponding to UO3·0.8–0.9H2O (Table 5). This non-stoichiometry is probably related to the substitution 2(OH)– = O2– + vacancy (Fig. 1; Finch et al. 1998), and the only single-crystal data available are for this material. Unfortunately the details of the synthesis of the crystal used by Taylor (1971) are not reported, but were part of a 1958 patent application (Harris and Taylor 1962).
Taylor (1971). In the following we use “α-UO₂(OH)₂” to refer to a stoichiometric compound with the crystal structure given by Taylor (1971), and “dehydrated schoepite” as a general term to designate compounds with stoichiometry UO₃⋅0.75–1.00H₂O and a unit cell closely related to that of α-UO₂(OH)₂; this usage includes paulscherrerite.

“Dehydrated schoepite” has been synthesized using several routes (Table 5; Fig. 8). Vochten and Blaton (1999) synthesized UO₃⋅0.8H₂O by heating synthetic rutherfordine, (UO)₂CO₃, in water at 100 °C for 30 days. Their TGA curve shows dehydration between 200 and 450 °C with a total loss of water (5.04 wt%) corresponding to 0.8 mole of water per U atom. Vochten and Blaton (1999) reported a powder pattern that shows clear evidence for monoclinic symmetry in their compound (doublet lines at 1.743/1.725 and 1.343/1.334 Å), as well as IR data similar to those obtained for paulscherrerite.

Unit cells refined on the basis of X-ray powder diffraction data for paulscherrerite, α-UO₂(OH)₂, and “dehydrated schoepite” synthesized using various different methods are summarized in Table 3. We succeeded in forming a mixture of metaschoepite and “dehydrated schoepite” simply by leaving amorphous UO₃[UO₃(am)] in air for two years. UO₃(am) was synthesized following the method of O’Hare et al. (1988) by roasting uranyl peroxide (made from uranyl nitrate) at 500 °C for 8 h. After 8 months, the orange product had turned yellow, and displayed broad diffraction lines characteristic of α-UO₂(OH)₂ (Fig. 9). After 24 months, the product was well crystallized, containing about 80% of paulscherrerite and 20% metaschoepite (Fig. 9; Table 3). Interestingly, this α-UO₂(OH)₂ does not display any evidence of monoclinic distortion, while the α-UO₂(OH)₂ prepared via hydrothermal method (G46) and a sample obtained from COGEMA showed evidence for such a distortion (Fig. 9; Table 3). While TGA curves of paulscherrerite and the COGEMA material are very similar—with all significant features appearing at similar temperatures—the material obtained by slow hydration of UO₃(am) in air has a more complex evolution. In particular, there is near-continuous water loss up to 235 °C in the latter material, while water (from metaschoepite admixtures) is lost by 150 °C in paulscherrerite and 195 °C in the COGEMA sample (Fig. 6). Correcting for the metaschoepite admixtures based upon water loss to 195 and 235...
**Figure 8.** Reactions among schoepite, metaschoepite, “dehydrated schoepite” (including paulscherrerite), and α-UO₂(OH)₂ based on natural occurrences and experimental studies (see text). Modified from Finch et al. (1998). Paulscherrerite at the type locality (Radium Ridge) forms via dehydration of metaschoepite (bold arrow) at T < 100 °C.

**Table 5.** Summary of results of previous studies of “dehydrated schoepite”: This table attempts to present an exhaustive view of the mentions of “dehydrated schoepite” in nature, as well as a selection of critical studies conducted on synthetic material.

°C, respectively, the empirical formula for “dehydrated schoepite” in the COGEMA sample is UO₃·0.9H₂O, and that from the sample left out for 24 months is UO₃·0.8H₂O.

Dawson et al. (1956) reported that UO₃(am) in contact with water at about 180 °C yields orthorhombic α-UO₂(OH)₂; and based on TGA results, they reported that the product was non-stoichiometric, with composition UO₃·0.8H₂O (Table 5). O’Hare et al. (1988) synthesized “dehydrated schoepite” using the same method, but at a lower temperature of 45–50 °C (5 days reaction time), and obtained the composition UO₃·0.9H₂O. Hoekstra and Siegel (1973) provide the best systematic characterization of “dehydrated schoepite” to date; they note that the unit cell, IR spectra, and TGA data for this phase vary slightly depending on the method of synthesis. Only material obtained via cooling of...
the β-UO₃(OH)₂ phase was stoichiometric [i.e., α-UO₂(OH)₂], while material prepared from UO₃(am) or γ-UO₂(OH)₂ contained less than one water pfu (UO₂·0.8H₂O) even when synthesized at 300 °C and 2 kbar. All the above studies agree that the formation of “dehydrated schoepite” is an irreversible process. In contrast, Sowder et al. (1999) obtained a compound with nominal composition UO₃·0.9H₂O (from TGA) by drying synthetic metaschoepite at 105–150 °C. This product quickly rehydrated to form poorly crystalline metaschoepite in water at room temperature. Unfortunately, the product is poorly characterized. The identity of their dehydration product with “dehydrated schoepite” is based on a single-crystal study, it is usually not possible to distinguish between an orthorhombic cell and a monoclinic cell with β close to 90° (e.g., Bevan et al. 2002). The only available single-crystal data for “dehydrated schoepite” are for a stoichiometric α-UO₂(OH)₂, probably synthesized via cooling of γ-UO₂(OH)₂ (Taylor 1971; Hoekstra and Siegel 1973).

Hence, there is currently no hard evidence that paulscherrerite from the Number 2 Workings is structurally different from the reported occurrences of “dehydrated schoepite” in nature. The confusion on the nature of “dehydrated schoepite” appears to have evolved from comparison between partial data sets obtained on material synthesized via different routes (e.g., Berlepsch et al. 2003 for a similar example). Further work is required to confirm and investigate the origin of the monoclinic distortion of paulscherrerite vs. α-UO₂(OH)₂, and about the variability in water content and stoichiometry of paulscherrerite, and its possible correlation with unit cell and symmetry. Polytypism is the most likely explanation for the slight structural variations affecting “dehydrated schoepite”; these do not warrant new mineral names, and are dealt with using suffixes (e.g., Guinier et al. 1984). In this context, the paulscherrerite type material provides a solid reference point on which to build our understanding of the nature of “dehydrated schoepite” in natural and engineered environments.

**Occurrences of paulscherrerite**

Recent assessment of the thermodynamics of metaschoepite and β-UO₂(OH)₂, by Kubatko et al. (2006) concluded that metaschoepite (and probably schoepite) may be metastable under all conditions. At 298.15 K, the Gibbs free energy for the reaction

\[ \text{UO}_2\cdot 2\text{H}_2\text{O (metaschoepite)} = \beta\text{-UO}_2\text{(OH)}_2 + \text{H}_2\text{O(l)} \]

is

\[ \Delta G_i = \Delta G_f(\text{UO}_2\cdot 2\text{H}_2\text{O}) + \Delta G_f(\text{H}_2\text{O}) - \Delta G_f(\beta\text{-UO}_2\text{(OH)}_2) = -1398.7 \pm 1.8 - 237.4 + 1632.0 \pm 4.0 = -4.1 \pm 4.4 \text{ kJ/mol}. \]

The enthalpy of formation of “dehydrated schoepite” with UO₂·0.9H₂O stoichiometry was measured using solution calorimetry by O’Hare et al. (1988) on material synthesized via hydration of UO₃(am) at 90 °C. For the reaction

\[ \text{UO}_2\cdot 2\text{H}_2\text{O (metaschoepite)} = \beta\text{-UO}_2\text{(OH)}_2 + \text{H}_2\text{O(l)} \]

the Gibbs free energy of reaction at standard conditions is

\[ \Delta G_i = \Delta G_f(\text{UO}_2\cdot 0.9\text{H}_2\text{O}) + 1.1\Delta G_f(\text{H}_2\text{O}) - \Delta G_f(\beta\text{-UO}_2\text{(OH)}_2) = -1374.4 \pm 2.6 - 1.1 \times 237.4 + 1632.0 \pm 4.0 = -3.5 \pm 4.8 \text{ kJ/mol}. \]

The Gibbs free energy for the transformation of β-UO₂(OH)₂ to UO₂·0.9H₂O at 25 °C is

\[ \beta\text{-UO}_2\text{(OH)}_2 = \text{UO}_2\cdot 0.9\text{H}_2\text{O} + 0.1\text{H}_2\text{O(l)} \]
\[ \Delta G_f = \Delta G_f^0(UO_2,0.9H_2O) + 1.1 \Delta G_f^0(H_2O) - \Delta G_f^0(\beta-UO_2(OH)_2) = -1374.4 \pm 2.6 - 0.1 \times 237.4 + 1398.7 \pm 1.8 = 0.6 \pm 3.2 \text{ kJ/mol}. \]

Overall, these calculations based on calorimetric results give little energy difference between metaschoepite, “dehydrated schoepite,” and \( \beta-UO_2(OH)_2 \), which suggests that kinetic effects probably play a major role in controlling the paths by which “dehydrated schoepite” forms (Fig. 8).

“Dehydrated schoepite” has been reported from several environments, as well as in many experimental studies dedicated to environmental uranium mineralogy or to using uraninite as analog for the UO\(_2\) found in some high-level radioactive waste. Paulscherrerite is a relatively common early alteration product of uraninite. Christ and Clarke (1960) analyzed “dehydrated schoepite” in schoepite crystals from Shinkolobwe (Katanga district, Democratic Republic of Congo), but showed that at least some of it may have formed from schoepite in the laboratory. Finch et al. (1992) and Finch and Ewing (1992) observed abundant “dehydrated schoepite” together with schoepite or metaschoepite as a weathering product of uraninite from the Shinkolobwe mine. They attributed the formation of the mineral to weathering under oxidizing near-surface conditions, in a monsoonal environment characterized by extremes of wet and dry conditions. Finch et al. (1992) showed that dehydration also occurred during museum storage of the specimen, and could be distinguished easily from environmental dehydration by the lack of overprinting by subsequent groundwater interaction. Pearl et al. (1994) described a similar occurrence at the Nopal I deposit, Chihuahua, Mexico. Korzub et al. (1997) identified “dehydrated schoepite” as an early product of uraninite weathering in the Ruggles and Palermo granitic pegmatites, New Hampshire, U.S.A.; they (erroneously) suggested a hydrothermal origin of the weathering (>100 °C) based on the lack of molecular water in paulscherrerite. Finally, Lind et al. (2009) identified “dehydrated schoepite” in soils contaminated during a fire at a depleted uranium (DU) ammunition storage facility in Kuwait in 1992, but not on DU impact residues in Kuwait or Kosovo.

Under oxidizing conditions, the solubility of uranium in solutions containing uraninite and other U\(^{4+}\)–bearing materials can be limited by the growth onto the leached surface of secondary phases such as uranyl hydrates and carbonates: effectively the aequous U-concentration becomes controlled by the newly formed uranyl minerals, and the solution remains heavily undersaturated with respect to uraninite (e.g., Trocellier et al. 1998). Several experimental studies regarding the rate of dissolution of uranium have observed the formation of “dehydrated schoepite.” “Dehydrated schoepite” appeared within a few days on the (104) surface of calcite was exposed to uranyl-bearing solutions of variable pH. In their acidic runs (initial pH 2.5, final 4.5) at 25 °C they observed the growth of schoepite, beccquerelite, and wyarithe-(II). The same experiment at 100 °C showed the initial presence of “dehydrated schoepite” that was replaced by beccquerelite after 2 to 3 days of contact time. Altogether, these experimental studies emphasize the importance of paulscherrerite as a transient product during weathering of uraninite/pitchblende and interaction between uranyl-rich groundwater and minerals.

Summer air temperatures at the Number 2 Workings commonly exceed 40 °C (Australian Bureau of Meteorology, Arkaoola station), and the surface rock temperature in the black massive hematite ore forming the gangue of paulscherrerite can exceed 70 °C. Transformation of metaschoepite to “dehydrated schoepite” has been observed in our study in water at 150 °C, and transformation of rutherfordite to “dehydrated schoepite” was observed at 100 °C by Vochten and Blaton (1999). The 70 °C temperature is also close to the conditions of the studies of Schindler et al. (2004), Kaminski and Goldberg (2002), and Trocellier et al. (1998) (90–100 °C), in which “dehydrated schoepite” was produced via interaction of water with U-rich material.

In summary, paulscherrerite appears to be a relatively common secondary mineral forming from the oxidation of uraninite and pitchblende. Although we applied state-of-the-art techniques to characterize paulscherrerite, we still do not have an adequate explanation why it is monoclinic and its close analog, synthetic \( \alpha-UO_2(OH)_2 \), is not. The significance of the variable UO\(_2\)H\(_2\)O reported in other studies of “dehydrated schoepite” (Table 5) also needs to be further investigated. In the absence of better single crystals of natural paulscherrerite, systematic studies using modern methods of “UO\(_2\)(OH)\(_2\)” \(^{	ext{1}}\) synthesized under a range of conditions and methods may help to understand the relationships between paulscherrerite and orthonhombic \( \alpha-UO_2(OH)_2 \), and the significance and extent of non-stoichiometry in these phases.

ACKNOWLEDGMENTS

Thanks to Daniel Baumann (Swiss Federal Institute of Technology, Lausanne) for performing the thermogravimetric and IR analyses and to Judge Bevan for discussions about crystallography. The manuscript benefitted from insightful comments by R. Finch, M. Cuney, R.L. Frost, J. Grice, R. Peterson, and E. Grew.
