SYNTHESIS OF LEAD PYROSILICATE AND OTHER BARYSILITE-LIKE COMPOUNDS

H. W. BILLHARDT,¹ Mineralogisches Institut der Universität (TH), Karlsruhe, Germany (BRD).

Abstract

In the binary system PbO-SiO₂ the compound $Pb_{8}Si_{2}O_{7}$ was synthesized. Indexed Xray powder and single crystal data as well as optical and IR data show that $Pb_{8}Si_{2}O_{7}$ is the Pb-analogue of the mineral barysilite $Pb_{8}Mn(Si_{2}O_{7})_{3}$. To elucidate the barysilite formula Pb in $Pb_{3}Si_{2}O_{7}$ has been partially replaced by Mn, Mg, Ca, Sr and Ba. A Pb-Sr-Ba-mixed crystal was synthesized which is isotypic but not isomorphic to natural barysilite. This Pb-Sr-Ba-"barysilite" probably has the formula $Pb_{8}(Pb, Sr, Ba)(Si_{2}O_{7})_{3}$. The ternary compound $2PbO \cdot MgO \cdot 2SiO_{2}$ found by Argyle and Hummel (1965/66) in the system PbO-MgO-SiO₂ was shown to be a Mg-"barysilite" of the composition $Pb_{8}Mg(Si_{2}O_{7})_{3}$.

INTRODUCTION

During the investigation of the ternary system PbO-SiO₂-SO₃ and the reexamination of the well known binary system PbO-SiO₂ the compound Pb₃Si₂O₇ was synthesized, probably in two modifications. This compound has often been searched for and has been discussed by many authors because it should correspond to the mineral barysilite. According to the mineral tables of Strunz (1966) barysilite has the formula Pb₃Si₂O₇ although in recent papers this formula has been considered as being too idealized. Thus Glasser (1964) suggested the formula Pb₄(Mn, etc)(Si₃O₁₁), but he failed to synthesize a barysilite of this composition. Lajzerowicz (1966) stated the barysilite formula as XPb₈·3(Si₂O₇); for natural barysilite X is mainly Mn. She prepared synthetic "barysilites" with X = Be, Mg, Ni, Co, Cu, Zn, Mn, Cd, Ca and Sr, but not a pure Pb-"barysilite." In 1967 Ito and Frondel suggested the formula MnPb₅(Si₂O₇)₂. Their efforts to get Pb₃Si₂O₇ even hydrothermally were unsuccessful.

In the system PbO-SiO₂ the compound Pb₃Si₂O₇ was first described by Krakau and Vakhrameev (1932), but in later investigations carried out by the same author and reported by Eitel (1965) it was not further mentioned. In 1939 Kordes reported the existence of Pb₃Si₂O₇ which he had obtained as hexagonal crystals and in 1962 Berezkina and Chizhikov gave a method of preparation for Pb₃Si₂O₇, and the first X-ray powder data which are in contradiction to the results presented here and discussed below. Without mentioning any details about Pb₃Si₂O₇ Argyle and Hummel (1965/66) accepted this compound in the system MgO-SiO₂-PbO. They also described a ternary compound 2PbO·MgO·2SiO₂

¹ Present address: Forschungsinstitut der Zementindustrie, 4 Düsseldorf-Nord, Germany (BRD). which, according to our investigations, is a Mg-"barysilite" of the composition $Pb_8Mg(Si_2O_7)_8$.

All other authors (Geller *et al.*, 1934; McMurdie *et al.*, 1939; Paetsch *et al.*, 1965; Argyle *et al.*, 1960) investigating the system PbO-SiO₂ doubted the existence of Pb₃Si₂O₇ or neglected the compound altogether.

PREPARATION OF Pb3Si2O7

Pure PbO and SiO₂ from E. Merck and R. de Haen were used for the preparation of Pb₃Si₂O₇. The oxides in stoichiometric relation were fused in Pt-crucibles at temperatures of about 950°C, taking into account the loss caused by evaporation. To protect the Pt-crucible from reaction with Pb a small amount of NH₄NO₃ was added to the sample in order to get an oxidizing atmosphere (Merker and Wondratschek 1967) and then the batch was heated very slowly. Glass of Pb₃Si₂O₇ composition was obtained by quenching the homogeneous melt.

Annealing experiments on "Pb₃Si₄O₇-glasses" showed no crystallization of Pb₃Si₂O₇ at 300°C after 24 hours. At 400–500°C, however, a microcrystalline phase X crystallized which is probably a low-temperature modification of lead pyrosilicate. This compound is stable up to about 650°C and decomposes at higher temperatures into lead orthosilicate Pb₂SiO₄ and lead metasilicate PbSiO₃. At 500–600°C another binary phase Y crystallizes from under-cooled melts, together with small amounts of Pb₂SiO₄ and PbSiO₃. This phase Y has an X-ray powder pattern similar to natural barysilite. It seems to decompose incongruently at about 710°C into Pb₂SiO₄ and melt. DTA-analyses show complete melting at 725 \pm 5°C.

Attempts to convert the high temperature phase Y into phase X by heating for 10 days at about 500°C failed. This may be due to a kinetic effect and does not rule out the possibility that X and Y are two modifications of the same compound. The X-ray powder diffraction pattern of X, however, is not similar to Y, but to a compound of pyromorphite type. Many lines could be indexed with hexagonal $a=9.94\pm0.02$ Å. The cell constant c could not be determined. Further investigations for the phase X are planned.

PREPARATIONS OF SINGLE CRYSTALS

Crystals of phase Y suitable for X-ray single crystal techniques were prepared by the following two methods:

1. Heating the quenched melt for several hours at about 650°C.

2. Quenching a melt to 680°C. When this temperature is reached, the cooling rate is retarded to about 5°C/min down to 650°C. At this temperature the sample is held for several hours. The cooling rate above 680°C should be not too slow, otherwise Pb₂SiO₄ crystallizes primarily. Pb₂SiO₄ is very stable and (together with the residual melt) cannot be converted into another compound, so that the metasilicate PbSiO₈ is formed out of the residual melt.

The second method of preparation is more successful than the first one. The single crystals thus obtained have irregular shapes and a cross-section of about 0.1 mm. Berezkina *et al.* (1962) got crystals in a glass matrix by quenching an undercooled melt that had been heated for 24 hours close to or below the melting point. They believed these crystals to have the composition $Pb_8Si_2O_7$ and to exist only near the melting point. Slow cooling was supposed to lead to decomposition of $Pb_8Si_2O_7$ to lead orthosilicate and metasilicate. This statement is in contradiction to our results described above. Experiments carried out under the conditions mentioned by Berezkina *et al.*, revealed that these crystals are a high tem-

perature modification of Pb₂SiO₄. The X-ray powder pattern, however, given by Berezkina *et al.* (FeK_{α}-radiation; 70–100 hours exposure time) could not be identified either with that of our phases X and Y or with any prepared PbSiO₃ or Pb₂SiO₄ modification (Billhardt, 1968).

X-RAY INVESTIGATIONS

Powder diffraction patterns of all compounds were made with an AEG-Guinier camera using pure Si-powder as an internal standard (Si, a=5.431 Å). Intensity measurements were made with a Zeiss-Jena photometer and the cell constants were refined and computed by the use of indexed powder diffraction patterns. In table 4 and 5 the *d*-values and intensities of phase X and Y are listed.

Oscillation and precession photographs of phase Y revealed hexagonal symmetry with the following conditions limiting possible reflexions:

$$\begin{array}{ll} hkil: & -h+k+l = 3n\\ (hh\overline{2}hl & l = 3n)\\ (h\overline{h}0l & h+l = 3n)\\ & \text{and } l = 2n \end{array}$$

This leads to the probable space groups R3c and R3c. The cell constants in hexagonal setting are: a = 10.13(6), c = 38.70(3) Å. By assuming Z = 18 for Pb₃Si₂O₇ the calculated density $\rho_{\text{(calc)}} = 6.86_4$ g/cm³ is in good agreement with the measured value $\rho_{\text{(meas)}} = 6.84 \pm 0.05$ g/cm³.

The comparison of these data with those of natural barysilite in Table 1 shows close agreement. The probable space group for barysilite of Långban/Sweden was determined as R3c or R3c, in agreement with J. Lajzerowicz, who assumed the space group R3c by investigating the systematic intensity distribution. The relationship between these two

TABLE 1. SINGLE CRYSTAL DATA OF BARYSI	lite and Pb ₃ Si ₂ O ₇
--	---

-	Barysilite, Långba	n	Synthetic Pb ₃ Si ₂ O ₇
This paper a = 9.80(1) Å c = 38.35(5) Å Z = 6 $\rho_{\text{(cale)}} = 6.91 \text{ g/cm}^3$	J. Lajzerowicz 9.821(5) Å 38.38 (6) Å 6 6.84 g/cm^3 $\rho_{(\text{meas})} = 6.72 \text{ g/cm}^3$ and 6.55–6.706 g/cm ³	F. P. Glasser ^a 8.46 (2)Å 38.3 (2)Å (Winchel, 1965) (Flink, 1917; referred by Glasser)	This paper $10.13 \pm 0.006 \text{ Å}$ $38.70 \pm 0.03 \text{ (Å)}$ 18 6.864 g/cm^3 $6.84 \pm 0.05 \text{ g/cm}^3$

^a The deviation from the cell constant *a* presented by Glasser (1964) is apparent. Most probably he erroneously published the $(a^x)^{-1}$ -value, because $a = (a^x)^{-1}/\sin 60^\circ = 9.77$ Å is in rather good agreement to the other values in Table 1. compounds is also indicated by the same optical character (negative birefringence) and similar IR-data. But while the mica-like platelets of barysilite and synthetic Mn-"barysilite" have excellent cleavage parallel to (001) no characteristic cleavage of phase Y was observed.

All investigations of phase Y and barysilite revealed that these two compounds are isotypic. According to the statement of J. Lajzerowicz that the natural barysilite has the formula $Pb_8Mn(Si_2O_7)_3$ the newly prepared phase Y has the composition $Pb_8Pb(Si_2O_7)_3$ and is the Pb-"barysilite" of the ideal composition $Pb_3Si_2O_7$.

Comparing the cell dimensions of barysilite and $Pb_3Si_2O_7$ in Table 1 it is evident that the substitution of Mn^{2+} by Pb^{2+} causes a considerable enlargement of the barysilite lattice. The synthesis of mixed crystals of Mn-"barysilite" and $Pb_3Si_2O_7$ was not possible. There were always two phases of different "barysilites." The ionic radii of Pb^{2+} and Mn^{2+} are too different for an isomorphic replacement in this structure. Therefore barysilite and $Pb_3Si_2O_7$ are isotypic but not isomorphic.

INFRARED DATA

With a Beckman Infrared Spectrophotometer IR 10 infrared spectra were recorded at liquid nitrogen temperatures, using KBr- and CsBrpellets. The absorption bands of phase X, $Pb_3Si_2O_7$ and barysilite are listed in Table 2. The absorption spectra of $Pb_3Si_2O_7$ and barysilite,

compared in Figure 1, are very similar except for the band near 700 cm⁻¹. This absorption band is characteristic for all pyrosilicates as have been pointed out by Lazarev (1961) and Lajzerowicz (1965). According to these authors the position of this band depends on the Si-O-Si-valence angle in the pyrosilicate structure which is a function of the Me²⁺-oxygen

FIG. 2. The position of the "characteristic pyrosilicate absorption band" of different "barysilites" as a function of the cation-oxygen distance. Small circles represent measurements of J. Lajzerowicz, large circles our own measurements.

distance. Therefore this characteristic pyrosilicate-band has been measured for all our synthesized "barysilites" and is compared with the data of J. Lajzerowicz in Figure 2.

This figure shows a good fitting of the data of the new Pb-"barysilite" and of the later described "barysilites" with large cations as Sr and Ba on the elongated line given for "barysilites" by J. Lajzerowicz.

SYNTHESIS OF Sr-Pb-Ba-"BARYSILITE" MIXED CRYSTALS

After the Pb-"barysilite" synthesis had been successful, the next step was to find out whether it is possible to replace Pb^{2+} by other large cations like Sr^{2+} and Ba^{2+} in the barysilite structure of $Pb_3Si_2O_7$.

The method of preparing these compounds was the same as described above for $Pb_3Si_2O_7$. However a treatment at higher temperatures was chosen (620–720°C). Besides pure PbO and SiO₂ the metal oxides SrO and BaO were used as reagents. These were obtained by thermal decomposition of their nitrates and carbonates under a nitrogen atmosphere (G. Brauer). The partial replacement of Pb by Sr and Ba in the barysilite structure led to the following mixed crystals:

> between Pb- and Sr-"barysilite" Pb- and Ba-"barysilite" Sr- and Ba-"barysilite"

The cell dimensions of these "barysilites" are tabulated in Table 3 and compared with the data of other "barysilites" in Figure 3.

TABLE 3. CELL DIMENSIONS OF Pb-Sr-Ba-"BARYSILITES"

* The tabulated chemical composition is that of the weighed-in material. Losses by evaporation can be neglected. Chemical analyses are difficult because it is not certain whether the samples were homogenous or whether there were also some small relicts of glass.

The synthesis of Ba-"barysilite" proved to be more difficult than that of Pb- and Sr-"barysilite." This may be due to the larger cation-radius of Ba²⁺. The synthesis of Mg- and Mn-"barysilite" (with small cations) is quite uncomplicated. This fact may explain why Pb-"barysilite" has never been found in nature up to now.

Mg-"BARYSILITE" IN THE SYSTEM PbO-MgO-SiO2

Only one ternary compound was synthesized by Argyle and Hummel (1965/66) during their investigation of the system PbO-MgO-SiO₂. They supposed that this compound 2PbO·MgO·2SiO₂ has the "unusual ability to take 2PbO·SiO₂, 3PbO·2SiO₂, PbOSiO₂, MgO·SiO₂ and SiO₂ into solid solution." They assumed that this was especially evident in the systems $2PbO\cdotSiO_2$ —2PbO·MgO·2SiO₂ and PbO·SiO₂—2PbO·MgO 2SiO₂. No change in the spacings of the "mixed crystals" was found. Therefore they explained this feature as caused by a "cation defect."

Now it was interesting to see whether the compound $2PbO \cdot MgO 2SiO_2$ has the barysilite structure or not. A comparison of the diffraction pattern of this "mixed crystal" given by Argyle and Hummel and of our natural barysilite shows good agreement in Table 6. We indexed the powder pattern of "2PbO \cdot MgO \cdot 2SiO₂" with the lattice spacing of our

516

FIG. 3. Cell dimensions of different "barysilites" as a function of the cation-oxygen distance. This figure of J. Lajzerowicz was extended with the data of Pb-Sr-Ba-"barysilites". Because there are no definite values of the cation-oxygen distance in the literature, these values are indicated as wide rectangles (compare also Fig. 2).

barysilite and calculated the cell dimensions $a_{\text{hex}} = 9.73(\pm 0.05)$, $c_{\text{hex}} = 38.24 \pm 0.1$ Å.

The density as measured by Argyle and Hummel is $\rho(\exp) = 6.15 \text{ g/cm}^3$. With this value the number of formula weights in the unit cell is Z = 19.12, whereas the theoretical value of Z for a barysilite is 18.

To elucidate this discrepancy we tried to synthesize a Mg-"barysilite." In the course of these efforts we observed two types of Mg-"barysilites":

Table 6. X-ray Powder Diffraction of Barysilite and Mg-"Barysilite" Compared with "Pd_MgSi_O7"

Mg-"barysilite" of type I is microcrystalline with broad and diffuse lines on the Guinier-X-Ray pattern and is obtained by quenching the melt. The cell dimensions are intermediate between those of Pb₃Si₂O₇ and type II described below. Probably Pb²⁺ replaces Mg²⁺ in the Mg-"barysilite" and enlarges the lattice constants.

Mg-"barysilite" of type II crystallizes by annealing type I at about 600–700°C or by cooling a melt slowly. Type II forms crystals which give sharp and distinct X-ray patterns. The characteristic IR absorption band for pyrosilicates moves from 703 cm⁻¹ for type I to 706 cm⁻¹ for type II.

In the hexagonal setting the cell constants of well-crystallized Mg-"barysilite" (type II) are: a=9.75(3), c=38.28(6) Å.

The density $\rho(\exp) = 6.83(\pm 0.1) \text{ g/cm}^3$ is in good agreement with the calculated density $\rho(\operatorname{calc}) = 6.91 \text{ g/cm}^3$ assuming Z = 6 for Pb₈Mg(Si₂O₇)₃.

Efforts to replace more than one of the nine Pb^{2+} by Mg $^{2+}$ failed. Therefore the formula of the ternary compound $2PbO \cdot MgO \cdot 2SiO_2$ in the system PbO-MgO-SiO₂ investigated by Argyle and Hummel (1965/ 66) could not be confirmed and is probably $Pb_8Mg(Si_2O_7)_3$.

DISCUSSION OF THE BARYSILITE FORMULA

According to their investigations of barysilite Ito and Frondel (1967) suggested the formula $Pb_{\delta}X(Si_2O_7)_2$. The number of formula weights per unit cell would then be Z=9. This would only be in agreement with the space group R3c or $R\overline{3}c$ determined by J. Lajzerowicz (1965) and given in this paper under the condition that X and Pb of Pb₈ are isomorphic. We never observed an isomorphic exchange of X and Pb of Pb₈. Therefore the formula Pb₅X(Si₂O₇)₂ is probably incorrect.

Chemical analyses of barysilite made by Bauer and Berman (1930) and G. Flink (reported by Glasser, 1964) have a Pb:X-ratio (X = Fe, Mn, Zn, Ca, Mg, K, Na) of about 4–5:1. Glasser interpreted these analyses as indicating the formula $3[Pb_4(Mn, etc)Si_3O_{11}]$. But even this formula is inconsistent with the single crystal data. Probably unpure barysilite was taken for these chemical analyses. As Ito and Frondel already pointed out, the barysilite X-ray powder diagram of Glasser contained nasonite Pb₆Ca₄[Cl₂/(Si₂O₇)₃].

Our experiments to replace more than one of the nine Pb cations by Sr, Ba and any other cation in "barysilite" failed. X-ray diffraction patterns and observations under the microscope always revealed some additional phases besides "barysilite." Therefore the proposed formula of Lajzerowicz $Pb_8X(Si_2O_7)_3$ is confirmed and the substituted cation X should occupy a special position in the barysilite structure.

ACKNOWLEDGEMENTS

The author expresses his thanks to Professor Dr. H. Wondratschek for his interest and support of this work. I am grateful to Dr. G. Weitz and Dr. W. E. Klee (Mineralogisches Institut der Universität Karlsruhe) for many helpful discussions.
