# $\mathrm{Ca}_{3} \mathbf{A l}_{2} \mathbf{P}_{2} \mathrm{Si}_{2} \mathrm{O}_{15}$ : new data and discussion 

N. Stirton, J. A. Gard and F. P. Glasser

Department of Chemistry, University of Aberdeen Meston Walk, Old Aberdeen AB9 2UE, Scotland

#### Abstract

The formula of $\mathrm{Ca}_{3} \mathrm{Al}_{2} \mathrm{P}_{2} \mathrm{Si}_{2} \mathrm{O}_{15}$ is confirmed by electron microprobe anlaysis and synthesis. Electron diffraction discloses that the crystals are monoclinic, $P a$ or $P 2 / a$. Powder X-ray data ( 80 reflections, 53 indexed) are presented. The refined cell dimensions are $a=24.212 \pm 0.008 \AA, b=5.110 \pm 0.003 \AA, c=10.698 \pm 0.003 \AA ; \beta=107.30 \pm 0.03^{\circ}$.

During the course of studies of the reaction products obtained by heating mixtures consisting mainly of apatite, $\mathrm{Na}_{2} \mathrm{CO}_{3}$ and $\mathrm{SiO}_{2}$, (Gunawardane and Glasser, 1979) we noted the possibility that feldspar might be present as an impurity and made a literature survey of compound formation in several relevant systems including $\mathrm{CaO}-\mathrm{Al}_{2} \mathrm{O}_{3}-\mathrm{P}_{2} \mathrm{O}_{5}-\mathrm{SiO}_{2}$. Simpson (1979) recently described the synthesis of a quaternary phase, $\mathrm{Ca}_{3} \mathrm{Al}_{2} \mathrm{P}_{2} \mathrm{Si}_{2} \mathrm{O}_{15}$, in this system and presented data for its characterization. We confirm the existence of a phase at this composition but disagree with some of his data and its interpretation.

Experiments were made using basically the same methods and techniques as described by Simpson. Starting materials included chemically-pure grades of $\mathrm{CaCO}_{3}, \mathrm{Al}_{2} \mathrm{O}_{3}, \mathrm{CaHPO} \mathrm{C}_{4}$ and finely-divided quartz containing $0.08 \%$ material which is not volatile with HF. It was convenient to prepare anorthite, $\mathrm{CAS}_{2}$, and $\mathrm{C}_{2} \mathrm{P}^{1}$ by firing weighed batches in Pt crucibles in air at $\sim 1300^{\circ} \mathrm{C}$ and $900^{\circ} \mathrm{C}$ respectively. The firings were repeated until a homogeneous product was obtained, as judged by optical microscopy and X-ray powder diffraction. $\mathrm{C}_{3} \mathrm{APS}_{2}$ was readily made by direct reaction of $\mathrm{CAS}_{2}$ and $\mathrm{C}_{2} \mathrm{P}$ in equimolar quantities ( $\sim 52 \mathrm{wt} . \% \mathrm{CAS}_{2}$ ). Preparations were also made containing 40 and $60 \mathrm{wt} . \%$ $\mathrm{CAS}_{2}$.

The products obtained by heating were examined by using a petrographic microscope; X-ray powder diffraction with a Hägg-Guinier focussing camera; CORA, an electron microscope equipped for chemical analysis in the transmission mode with an energy dispersive attachment; and by electron diffrac-

[^0]tion using an AEI instrument equipped with a double-tilt stage developed by Gard (1976).

Preparations at the $\mathrm{C}_{3} \mathrm{APS}_{2}$ ratio appeared microscopically homogeneous at subsolidus temperatures. At $1325^{\circ} \mathrm{C}$, the product consisted of small, anhedral to platy crystals of low birefringence, wavy or undulose extinction and a mean refractive index close to 1.57 . Traces of glass were also found. At $1355^{\circ} \mathrm{C}$, incongruent melting had occurred and the product consisted of $\mathrm{C}_{3} \mathrm{P}$ and glass. Preparations containing 40 and $60 \mathrm{wt} . \% \mathrm{CAS}_{2}$ contained notably less $\mathrm{C}_{3} \mathrm{APS}_{2}$, and at $1260^{\circ} \mathrm{C}$ consistently contained $\mathrm{C}_{3} \mathrm{APS}_{2}$ and glass together with an excess of either $\mathrm{C}_{3} \mathrm{P}$ or $\mathrm{CAS}_{2}$, respectively. The crystals obtained from the $\mathrm{C}_{3} \mathrm{APS}_{2}$ batch were too small for single-crystal X-ray diffraction, and were analyzed by electron optical methods. Table 1 shows the analyses obtained from 20 crystals in the $\mathrm{C}_{3} \mathrm{APS}_{2}$ batch. The analytical results corroborate the formula for this phase proposed by Simpson. The glass produced by partial incongruent melting of the $\mathrm{C}_{3} \mathrm{APS}_{2}$ composition had the approximate ratio (based on 10 analyses) $\mathrm{C}_{1.00} \mathrm{~A}_{1.33} \mathrm{P}_{0.92} \mathrm{~S}_{2.78}$, and is thus enriched in $\mathrm{Al}_{2} \mathrm{O}_{3}$ and $\mathrm{SiO}_{2}$ components as would be expected because incongruent melting to yield $\mathrm{C}_{3} \mathrm{P}$ had occurred.

Electron diffraction measurements were made using Al as an internal standard. Projections of the reciprocal lattice were constructed from zones recorded while tilting crystals about various rows of spots, particularly those spaced at $(11.58 \AA)^{-1}$ and $(5.12 \AA)^{-1}$. Figure 1 shows four examples of these zones. Rotation around the $(5.12 \AA)^{-1}$ axis gave zones with spots on orthogonal meshes, including the zones shown in Figs. 1(c) and (d). The sharp spots on all the zones recorded could be indexed on a primitive monoclinic pseudo-cell with $a=12.14$,

Fig. 1. Electron diffraction patterns of $\mathrm{Ca}_{3} \mathrm{Al}_{2} \mathrm{P}_{2} \mathrm{Si}_{2} \mathrm{O}_{15}$, with the following zone axes parallel to the electron beam: (a) [010], (b) [011], (c) [001], (d) [100]. Note the elongated odd- $h$ spots in (b) and (c). The rings are from $\mathrm{Al}\left(d_{111}=2.338 \AA, d_{020}=2.025 \AA\right.$ ).
$b=5.12, c=10.72 \AA, \beta=107.3^{\circ}$, with no extinctions. From the [010] orientation giving the distorted hexagonal zone shown in Figure 1(a), however, tilting about the $a^{*}$-axis gives zones (e.g., Figs. 1(b) and (c)) in which elongated weaker spots interspace the sharp spots in all rows parallel to $a^{*}$ (odd $h 00$ spots are extinctions, but these spots are present due to multiple diffraction). This shows that the true
unit cell is also primitive monoclinic, with $a=$ $24.28, b=5.12, c=10.72 \AA, \beta=107.3^{\circ}$, with some stacking disorder. Absence of the weak spots with $h$ odd from the $h 0 l$ zone (Fig. 1(a)) indicates an $a$-glide normal to $b$, corresponding to possible space groups $P a$ (No. 7) or P2/a (No. 13).

The indexing of the powder pattern was initiated with the approximate pseudocell dimensions ob-

Table 1. Transmission electron microscope analyses of $\mathrm{C}_{3} \mathrm{APS}_{2}$ crystals

tained from electron diffraction and a powder pattern whose $d$ spacings were read with an optical microdensitometer and corrected relative to a Si internal standard ( $a=3.1355 \AA$ ). A few closelyspaced pairs of reflections were resolved with the aid of a travelling vernier microscope. As the indexing was extended to include progressively more reflections and the cell parameters refined by successive least-squares cycles, it became apparent that even the purest preparation contained a small amount of an unidentified phase. Powder reflections from this phase were excluded from the refinement. The reflections thus excluded, relative to the strongest reflection of $\mathrm{C}_{3} \mathrm{APS}_{2}$ at $2.83 \AA$ corresponding to 100 , had intensity $\leq 7$ : hence we are unable to rank them accurately in order of intensity, but reflections thus excluded were consistently observed at $d=8.10,6.47,3.45$ and $2.74(\AA)$. These reflections do not match the patterns of the starting materials ( $\mathrm{CAS}_{2}, \mathrm{C}_{2} \mathrm{P}$ ) or of likely impurities, e.g., $\mathrm{C}_{3} \mathrm{P}$. The indexed pattern, containing only reflections due to $\mathrm{C}_{3} \mathrm{APS}_{2}$, is shown in Table 2.

The density of the purest $\mathrm{C}_{3} \mathrm{APS}_{2}$ preparation, determined using an air-comparison pycnometer, was $2.795 \pm 0.003 \mathrm{~g} \mathrm{~cm}^{-3}$. The volume of the unit cell, determined using the refined pseudocell parameters, is $631.46 \AA^{3}$. Assuming that the empirical formula $\mathrm{C}_{3} \mathrm{APS}_{2}$ is correct, the number of formula units per cell, $\mathrm{Z},=1.998$ (or 2 ).

The occurrence, composition, optical properties and melting point determined in the course of the present study are in reasonable agreement with those reported by Simpson. Thus it would appear that the same phase has been obtained in both studies. The agreement between the two sets of powder data is less satisfactory. For example, not only do the two sets of $d$ spacings differ by a

This reflection may contain a contribution from a tricalcium phosphate solid solution.
variable and often significant extent, but Simpson also finds reflections occurring at $d$ values which are absent from our pattern, e.g., at 7.74 and $6.23 \AA$. It would appear that the triclinic cell was generated using a trial-and-error method, unassisted by single
crystal measurements or even optical measurements indicative of crystal symmetry. The indexing on the basis of a large triclinic cell is therefore highly suspect as it appears (1) that not all the reflections included in the refinement belong to $\mathrm{C}_{3} \mathrm{APS}_{2}$, and (2) that some reflections belonging to $\mathrm{C}_{3} \mathrm{APS}_{2}$ went unobserved and were not included.

It is not practicable to guess the structure type from the knowledge of the cell dimensions. The layer structure postulated by Simpson may or may not be correct, but in our experience cell dimensions alone are inadequate to admit sufficient deduction of even the general features of the structures of the chemically complex, low-symmetry phases.
