# Optic axial angle, a precise measure of Al,Si ordering in $\mathrm{T}_{1}$ tetrahedral sites of K-rich alkali feldspars 

S. C. Su, ${ }^{1}$ F. D. Bloss, P. H. Ribbe<br>Department of Geological Sciences<br>Virginia Polytechnic Institute and State University Blacksburg, Virginia 24061<br>and D. B. Stewart<br>U. S. Geological Survey<br>959 National Center, Reston, Virginia 22092

#### Abstract

For most K-rich alkali feldspars, the optic axial angle $2 V_{x}$ provides a precise estimate of the total Al content $\left(=\Sigma \mathrm{t}_{1}\right)$ of the $\mathrm{T}_{1}$ tetrahedral sites. For monoclinic varieties with the optic axial plane (OAP) parallel to ( 010 ), $$
\Sigma \mathrm{t}_{1}=2 \mathrm{t}_{1}=0.665-0.711 \sin ^{2} V_{\mathrm{x}} .
$$

For monoclinic varieties with the OAP perpendicular to (010) and for triclinic varieties with the OAP nearly perpendicular to ( 010 ), $$
\Sigma \mathrm{t}_{1}=\mathrm{t}_{1} \mathrm{o}+\mathrm{t}_{1} \mathrm{~m}=0.665+0.711 \sin ^{2} V_{\mathrm{x}} .
$$

These equations represent two segments of a line derived by least-squares regression performed on literature data for 52 specimens ( 19 with structural refinements) for which $\Sigma t_{1}$ values were calculated from cell parameters using the [110],[11 0$]$ method of Kroll (1980). The standard error of estimate is $0.02 ; r^{2}=0.962$. Thus by use of a spindle stage or universal stage, one can rapidly and precisely determine the "structural state" for individual grains or, in thin sections, from point to point in a single grain. For the feldspars used in the regression, no account was taken of their symmetry, of the albite content (up to $20 \mathrm{~mol} \%$ ), of minor amounts of $\mathrm{Ca}, \mathrm{Ba}, \mathrm{Sr}$, or Fe , or of the possible effects of strain or submicroscopic twinning or exsolution, indicating that these factors may be disregarded in using these equations. The changes in optic orientation and $2 V_{\mathrm{x}}$ as $\mathrm{Al}, \mathrm{Si}$ order increases from high sanidine $[\mathrm{OAP}=(010)]$ to orthoclase $[\mathrm{OAP} \perp(010)]$ to low microcline $[\mathrm{OAP} \sim \perp(010)]$ are explained by assuming a simple linear variation in principal refractive indices with structural state.

## Introduction

It is well known that the optic axial angle $2 V_{\mathrm{x}}$ is strongly dependent on the long-range order of $\mathrm{Al}, \mathrm{Si}$ in the tetrahedral sites of K -rich feldspars, and in fact $2 V_{x}$ has been used to designate relative "structural states" for many years (see Smith, 1974, Chapter 8, for a review). Conventionally, the highly disordered, monoclinic high sanidines (HS) have optic axial planes (OAP's) parallel to (010) with $2 V_{\mathrm{x}}$ ranging from $\sim 60^{\circ}$ to $0^{\circ}$; low sanidines (LS) have OAP's normal to (010) with $0^{\circ}<2 V_{\mathrm{x}}<-36^{\circ}$;

[^0]orthoclases (OR) also have OAP's $\perp$ (010), but with $\sim 36^{\circ}$ $<2 V_{\mathrm{x}}<\sim 80^{\circ}$. Triclinic microclines (MC) have OAP's approximately normal to ( 010 ) with $2 V_{\mathrm{x}}$ values overlapping the orthoclases and vary from $\sim 38^{\circ}$ (intermediate microclines) to $\sim 85^{\circ}$ for completely ordered low or maximum microcline (LM). ${ }^{2}$ Thus, combined with the change in orientation of the optic plane, $2 V_{\mathrm{x}}$ varies through a

[^1]total of $145^{\circ}$ as $\mathrm{Al}, \mathrm{Si}$ ranges from disordered to ordered in K-rich alkali feldspars.
The crystal structures of potassic feldspars are well documented by 15 or more modern structural refinements of $C 2 / m$ sanidines and orthoclases and another 15 of $C \overline{1}$ microclines. These have led to a detailed understanding of the response of unit cell parameters-notably $b, c, \alpha^{*}$ and $\gamma^{*}$-to changes in Al,Si distribution within the two tetrahedral sites ( $\mathrm{T}_{1}$ and $\mathrm{T}_{2}$ ) of monoclinic potassic feldspars and among the four tetrahedral sites ( $\mathrm{T}_{1} \mathrm{o}, \mathrm{T}_{1} \mathrm{~m}, \mathrm{~T}_{2} \mathrm{O}$ and $T_{2} \mathrm{~m}$ ) of triclinic ones. Using the symbols $\mathrm{t}_{1}, \mathrm{t}_{2}, \mathrm{t}_{1} \mathrm{O}$, $\mathrm{t}_{1} \mathrm{~m}, \mathrm{t}_{2} \mathrm{O}$ and $\mathrm{t}_{2} \mathrm{~m}$ to designate the average $\mathrm{Al} /(\mathrm{Al}+\mathrm{Si})$ contents of these sites (as determined from mean $\mathrm{T}-\mathrm{O}$ bond lengths in the aforementioned structural refinements), we may make the following statements about K rich alkali feldspars: (1) For $\mathrm{C} 2 / \mathrm{m}$ monoclinic specimens: $2 \mathrm{t}_{1}+2 \mathrm{t}_{2}=1.0$. (2) For $C \overline{1}$ triclinic specimens: $\mathrm{t}_{1} \mathrm{o}+\mathrm{t}_{1} \mathrm{~m}+$ $\mathrm{t}_{2} \mathrm{O}+\mathrm{t}_{2} \mathrm{~m}=1.0$. (3) The most disordered high sanidine has $2 t_{1}=2 t_{2}=0.5$ (although this has never been observed in a natural specimen). (4) In low sanidines and orthoclases $2 t_{1}$ becomes increasingly greater than $2 t_{2}$ as ordering increases. (5) Microclines have $\mathrm{t}_{1} \mathrm{o}>\mathrm{t}_{1} \mathrm{~m}>\mathrm{t}_{2} \mathrm{O} \simeq \mathrm{t}_{2} \mathrm{~m}$ or $\mathrm{t}_{1} \mathrm{O}>\mathrm{t}_{1} \mathrm{~m} \simeq \mathrm{t}_{2} \mathrm{O} \simeq \mathrm{t}_{2} \mathrm{~m}$. (6) Ordered low microcline has $\mathrm{t}_{1} \mathrm{O}=1.0, \mathrm{t}_{1} \mathrm{~m}=\mathrm{t}_{2} \mathrm{O}=\mathrm{t}_{2} \mathrm{~m}=0.0$. Kroll and Ribbe (1983) give details on how to estimate Al contents of T sites from crystal structure data and from unit cell parameters determined by X-ray single-crystal or powder diffractometry. In this paper, however, we present the quantitative relationship between the total Al content of the $\mathrm{T}_{1}$ sites, $\Sigma \mathrm{t}_{1} \equiv 2 \mathrm{t}_{1}$ or $\left(\mathrm{t}_{1} \mathrm{o}+\mathrm{t}_{1} \mathrm{~m}\right)$, and $2 V_{\mathrm{x}}$, thus establishing a rapid and precise method of determining the structural state of separated grains of K-rich alkali feldspars (using a spindle stage) or from point to point on grains in thin section (using a universal stage).

## The relation of optical properties to $\mathrm{Al}, \mathrm{Si}$ distribution

Disordered high sanidine ( $\Sigma \mathrm{t}_{1} \simeq 0.5$ ) and ordered low microcline ( $\Sigma \mathrm{t}_{1} \simeq 1.0$ ) differ markedly in optic orientation (Fig. 1). Consequently, to facilitate comparison of principal refractive indices for light vibrating along similar crystallographic directions in these two structures (and in those of intermediate structural states), we use $n_{\mathrm{b}}$ to symbolize the principal index for light vibrating parallel or nearly parallel to the crystallographic axis $\mathbf{b}$. In this we follow Hewlett (1959), who used the symbol 'b"' (see also Finney and Bailey, 1964). We extend this convention by using $n_{\mathrm{a}}$ and $n_{\mathrm{c}}$ to indicate the principal refractive indices for light vibrating most nearly parallel to the a and $\mathbf{c}$ crystallographic axes, respectively, even though these vibrations may be at appreciable angles to a and $c$.

## Refractive indices versus unit cell edges

If at opposite ends of a "structural state" scale we plot the principal refractive indices for high sanidine (HS) and low microcline (LM) and label them $n_{\mathrm{a}}, n_{\mathrm{b}}, n_{\mathrm{c}}$ instead of

Fig. 1. The optic orientations of high sanidine and low microcline. Dashed lines are the traces of the optic axial planes.
$\alpha, \beta, \gamma$, and if we simplistically assume that $n_{\mathrm{a}}, n_{\mathrm{b}}$ and $n_{\mathrm{c}}$ vary linearly with total Al content of the $\mathrm{T}_{1}$ sites, the lower portion of Figure 2 results. The general correctness of this model over that in which $\gamma_{\mathrm{HS}}$ is traditionally connected to $\gamma_{\mathrm{LM}}$ and $\beta_{\mathrm{HS}}$ to $\beta_{\mathrm{LM}}$, is readily apparent. It indicates that, for OAP $=(010)$ in HS, $2 V_{\mathrm{x}}$ decreases from $\sim 60^{\circ}$ to $0^{\circ}$ with increased $\mathrm{Al}, \mathrm{Si}$ ordering. With continued $\mathrm{Al}, \mathrm{Si}$ ordering beyond the point where $n_{\mathrm{b}}$ equals $n_{c}$, the OAP becomes perpendicular to (010) or nearly so, and $2 V_{\mathrm{x}}$ increases from $0^{\circ}$ toward its maximum value of $\sim 85^{\circ}$ for LM. Cell-edge data for HS and LM also corroborate this model. If we add these data to Figure 2 and for simplicity assume linear variation, we note a reciprocal relationship between each cell edge and the principal refractive index for light vibrating most nearly parallel to it. Thus, as $\mathrm{Al}, \mathrm{Si}$ ordering increases from HS to LM, a marked increase in $n_{\mathrm{b}}$ accompanies a marked decrease in $b$, a slight increase in $n_{\mathrm{a}}$ accompanies a slight decrease in $a$, and a marked decrease in $n_{c}$ accompanies a marked increase in $c$. This principle of the inverse relationship between cell-edge length and corresponding refractive index was first demonstrated convincingly for the andalusite-kanonaite series by Gunter and Bloss (1982) and, indeed, aided our insight into the alkali feldspars. In Figure 2 we arbitrarily chose to plot $b$ and $c$ so that they cross at the $\Sigma \mathrm{t}_{1}$ value for which $n_{\mathrm{b}}=n_{\mathrm{c}}$ in our model. This emphasizes the reciprocity between the refractive index and its corresponding cell edge by causing the triangles formed by the intersection of lines $b$ and $c$ to be very similar to the two formed by the intersection of lines $n_{c}$ and $n_{\mathrm{b}}$.

Hewlett (1959) recognized that the $d_{010}$ and $d_{001}$ spacings varied nearly linearly with structural state of K-rich feldspars, and Stewart and Ribbe (1969) quantified these relationships for the $b$ and $c$ cell edges of all alkali feldspars. In Figure 3 it can be seen that the Al contents encountered in any six contiguous tetrahedral sites along $b\left(\equiv \mathrm{Al}_{\mathrm{b}}\right)$ and any three along $c\left(\equiv \mathrm{Al}_{\mathrm{c}}\right)$ are:

$$
\begin{equation*}
\mathrm{Al}_{\mathrm{b}}=\mathrm{t}_{1} \mathrm{o}+\mathrm{t}_{1} \mathrm{~m}+4 \mathrm{t}_{2} \tag{1}
\end{equation*}
$$

and

$$
\begin{equation*}
\mathrm{Al}_{\mathrm{c}}=\mathrm{t}_{1} \mathrm{O}+\mathrm{t}_{1} \mathrm{~m}+\mathrm{t}_{2} \tag{2}
\end{equation*}
$$

Fig. 2. The refractive indices, $n_{\mathrm{a}}, n_{\mathrm{b}}, n_{\mathrm{c}}$ (open circles), and unit cell dimensions, $a, b, c$, (open squares), are plotted for high sanidine (HS) and low microcline (LM), and simple linear variations are assumed for each parameter. The $n$ values for HS were determined by refinement of values extrapolated from data given by Smith (1974, Figs. 8-9, p. 386); the corresponding $2 V_{x}$ $=46.4^{\circ}$. The $n$ values for LM are those of the Pellotsalo specimen of Brown and Bailey (1964); $2 V_{x}=82.3^{\circ}$. The cell dimensions of HS ( $2 \mathrm{t}_{1}=0.56$ ) and LM ( $\mathrm{t}_{1} \mathrm{O}=1.0$ ) are those chosen by Kroll and Ribbe (1983) as standard reference values for alkali feldspars [see their paper (pp. 71 and 74 and Table 4) for details and reasons for choosing to plot HS at $\Sigma \mathrm{t}_{1}=0.56$; this choice controls the values of $\alpha_{\mathrm{s}}, \beta_{\mathrm{s}}, \gamma_{\mathrm{s}}$, and the coefficients in Equations 8 and 9]. The $\mathrm{Al}_{\mathrm{b}}, \mathrm{Al}_{\mathrm{c}}$ (upper abscissa) and $\Sigma \mathrm{t}_{1}$ (lower abscissa) scales are linearly related (Equations 4 and 5). The sigmoidal curve of $2 V_{x}$ versus $\Sigma t_{1}$ was calculated in the manner described in the text; data from Table 1 were subsequently added. For an earlier version, see Su et al. (1983a).
where $t_{2}$ represents $t_{2} \mathrm{O}$ or $\mathrm{t}_{2} \mathrm{~m}$ for triclinic feldspars (in which all structure analyses to date have shown $\mathrm{t}_{2} \mathrm{O}=$ $t_{2} \mathrm{~m}$ ). Because

$$
\begin{gathered}
\mathrm{t}_{1} \mathrm{o}+\mathrm{t}_{1} \mathrm{~m}+\mathrm{t}_{2} \mathrm{o}+\mathrm{t}_{2} \mathrm{~m}=1 \\
\text { or } \Sigma \mathrm{t}_{1}+\mathrm{t}_{2} \mathrm{o}+\mathrm{t}_{2} \mathrm{~m}=1
\end{gathered}
$$

and since $\mathrm{t}_{2} \mathrm{O}=\mathrm{t}_{2} \mathrm{~m}$,

$$
\begin{equation*}
\mathrm{t}_{2}=\frac{1}{2}\left(1-\Sigma \mathbf{t}_{1}\right) \tag{3}
\end{equation*}
$$

Equations 1 and 2 may be rewritten

$$
\begin{equation*}
A l_{b}=\Sigma t_{1}+2\left(1-\Sigma t_{1}\right)=2-\Sigma t_{1} \tag{4}
\end{equation*}
$$

and

$$
\begin{equation*}
A l_{c}=\Sigma t_{1}+\left(1-\Sigma t_{1}\right) / 2=\left(1+\Sigma t_{1}\right) / 2 \tag{5}
\end{equation*}
$$

To a first approximation, therefore, the amounts of Al encountered along $b$ and $c$ are linear functions of $\Sigma \mathrm{t}_{1}$ (see upper abscissa in Fig. 2), Al $\mathrm{Al}_{\mathrm{b}}$ decreasing from 1.5 for HS to 1.0 for LM and $\mathrm{Al}_{\mathrm{c}}$ increasing exactly half as much, that is, from 0.75 for HS to 1.0 for LM. Because the effective size of Al is larger than Si (mean $\mathrm{T}-\mathrm{O}$ bonds are $\sim 1.74 \AA$ for Al sites, $\sim 1.61 \AA$ for Si sites), Stewart and Ribbe (1969) were able to show that the cell edges $b$ and $c$ vary proportionately with $\Sigma \mathrm{t}_{1}$, as now confirmed by approximately 30 crystal structures (Kroll and Ribbe, 1983). By contrast, the cell edge $a$ varies only slightly with $\mathrm{Al}, \mathrm{Si}$ ordering because

$$
\mathrm{Al}_{\mathrm{a}}=\mathrm{t}_{1} \mathrm{O}+\mathrm{t}_{1} \mathrm{~m}+\mathrm{t}_{2} \mathrm{O}+\mathrm{t}_{2} \mathrm{~m}=1.0
$$

and the actual distribution of Al among these sites is essentially irrelevant to the length of $a$.

## Sigmoidal $2 V_{x}$ curve

We now assume that the refractive indices and their linear variation with Al ,Si ordering are reasonably correct (Fig. 2). From these refractive index trends, we can

Fig. 3. The arrangement of tetrahedra along $b$ and $c$ in similar regions of the unit cells of high sanidine (HS) and low microcline (LM). The tetrahedra are ruled roughly in proportion to their Al content ( 0.25 for each T site in HS; 1.0 for $\mathrm{T}_{1} \mathrm{O}$ in ordered LM).
calculate $2 V_{\mathrm{x}}$ using the exact equation

$$
\begin{equation*}
\sin ^{2} V_{\mathrm{x}}=\frac{\beta^{-2}-\gamma^{-2}}{\alpha^{-2}-\gamma^{-2}} \tag{6}
\end{equation*}
$$

or, to within a few tenths of a degree for crystals of low birefringence like potassic feldspars, using the approximate equation

$$
\begin{equation*}
\sin ^{2} V_{x}=\frac{\gamma-\beta}{\gamma-\alpha} . \tag{7}
\end{equation*}
$$

Plotting $2 V_{\mathrm{x}}$ values calculated from the linearly varying refractive indices against $\Sigma \mathrm{t}_{1}$ produces the sigmoidal curve shown near the top of Figure 2. To this curve we
sured by powder methods on the $K$-rich phase only (Stewart and Wright, 1974); these parameters were used to calculate $\Sigma \mathrm{t}_{1}$. Since "geologic evidence is abundant for a range in $2 V_{x}$ of tens of degrees in one feldspar crystal, and of $50^{\circ}$ or more among the crystals in a single hand specimen" (Stewart and Ribbe, 1983, p. 133), it is remarkable how good the agreement is with the sigmoidal curve.
A corollary of the assumed linear variation of $n_{\mathrm{a}}, n_{\mathrm{b}}$ and $n_{\mathrm{c}}$ relative to $\Sigma \mathrm{t}_{1}$ (Fig. 2) is that the birefringences $(\gamma-\alpha)$, $(\gamma-\beta)$ and $(\beta-\alpha)$ also vary linearly with $\Sigma \mathrm{t}_{1}$. These linear relationships, if used in conjunction with equation 6 , will lead to the following general equations for the sigmoidal curve (after considerable mathematical manipulation). Thus, for $\mathrm{OAP}=(010)$ we obtain:

$$
\begin{equation*}
\Sigma t_{1}=0.44\left[\frac{\left(\gamma_{\mathrm{s}}-\beta_{\mathrm{s}}\right)-\left(\gamma_{\mathrm{s}}-\alpha_{\mathrm{s}}\right) \sin ^{2} V_{\mathrm{x}}}{\left[\left(\gamma_{\mathrm{m}}-\beta_{\mathrm{m}}\right)+\left(\gamma_{\mathrm{s}}-\beta_{\mathrm{s}}\right)\right]+\left[\left(\beta_{\mathrm{m}}-\alpha_{\mathrm{m}}\right)-\left(\gamma_{\mathrm{s}}-\alpha_{\mathrm{s}}\right)\right] \sin ^{2} V_{\mathrm{x}}}\right]+0.56 \tag{8}
\end{equation*}
$$

For OAP $\perp(010)$ or $\sim \perp(010)$ we obtain:

$$
\begin{equation*}
\Sigma \mathrm{t}_{1}=0.44\left[\frac{\left(\gamma_{\mathrm{s}}-\beta_{\mathrm{s}}\right)-\left(\beta_{\mathrm{s}}-\alpha_{\mathrm{s}}\right) \sin ^{2} V_{\mathrm{x}}}{\left[\left(\gamma_{\mathrm{m}}-\beta_{\mathrm{m}}\right)+\left(\gamma_{\mathrm{s}}-\beta_{\mathrm{s}}\right)\right]+\left[\left(\gamma_{\mathrm{m}}-\alpha_{\mathrm{m}}\right)-\left(\beta_{\mathrm{s}}-\alpha_{\mathrm{s}}\right)\right] \sin ^{2} V_{\mathrm{x}}}\right]+0.56 \tag{9}
\end{equation*}
$$

added data from the literature for which $2 V_{\mathrm{x}}$ and unit cell parameters were both reported (Table 1) so that $\mathrm{t}_{1} \mathrm{o}$ and $\mathrm{t}_{1} \mathrm{~m}$ could be calculated for each specimen using the [110],[110] translation method of Kroll (1980, reported in Kroll and Ribbe, 1983). Most of these data points fall very close to the sigmoidal curve. In fact, the estimated standard error in $\Sigma \mathrm{t}_{1}$ is 0.02 for 52 specimens, 19 of which have known crystal structures that confirm the $\Sigma \mathrm{t}_{1}$ values calculated by Kroll's method (see Table 2).
The agreement between the sigmoidal model and the crystal data is all the more remarkable because: (1) No consideration was given to whether the crystal symmetry was monoclinic or triclinic; (2) No correction for albite content was made even though some specimens contained up to $20 \mathrm{~mol} \% \mathrm{Ab}$, in addition to minor amounts of $\mathrm{Ca}, \mathrm{Ba}, \mathrm{Sr}$, and Fe ; (3) Some of the specimens are submicroscopically twinned and/or exsolved; (4) Some specimens may be strained; (5) The sigmoidal curve, in the final analysis, was derived from just two sets of data points (HS and LM; data on Fig. 2) together with the simplistic assumption that refractive indices $n_{\mathrm{a}}, n_{\mathrm{b}}$ and $n_{\mathrm{c}}$ vary linearly with $\mathrm{Al}, \mathrm{Si}$ ordering between HS and LM ; (6) For 32 of these data, cell parameters were measured on powdered specimens and $2 V_{\mathrm{x}}$ on separate crystals, and even some of the specimens whose crystal structures were determined had their $2 V_{x}$ values measured on separate single crystals. Only eight of the nine feldspars in the superb suite of Dal Negro et al. (1978) and DePieri (1979) are certain to have had $2 V_{x}$ and $\Sigma t_{1}$ (from both cell parameters and structure analyses) measured on the same grain! In fact, some of the specimens in Table 1 had $2 V_{\mathrm{x}}$ measured by Spencer (1937) and cell parameters mea-

Here the subscripts $s$ and $m$ respectively are abbreviations for HS and LM. To the extent that the refractive index data plotted in Figure 2 are correct, equation 8 becomes

$$
\begin{equation*}
\Sigma \mathrm{t}_{1}=1.686-\frac{1.626}{1.600-\sin ^{2} V_{\mathrm{x}}} \tag{10}
\end{equation*}
$$

and equation 9 becomes

$$
\begin{equation*}
\Sigma \mathrm{t}_{1}=-1.024+\frac{4.517}{2.667-\sin ^{2} V_{\mathrm{x}}} \tag{11}
\end{equation*}
$$

Also, to the extent these refractive indices and equations 10 and 11 are valid, the cross-over point of the sigmoidal curve (i.e., the point where $V_{\mathrm{x}}=0^{\circ}$ ) occurs at $\Sigma \mathrm{t}_{1}=0.67$.

## Linear model: $\Sigma t_{1}$ versus $\sin ^{2} V_{x}$

Equation 7 indicates that $\sin ^{2} V_{\mathrm{x}}$ represents the quotient of two birefringences. Even if both birefringences vary linearly with $\Sigma t_{1}$, their quotient and thus $\sin ^{2} V_{\mathrm{x}}$ would not do so (see the discussion by Bloss, 1952). Equations 10 and 11 also indicate that $\Sigma \mathrm{t}_{1}$ is related nonlinearly to $\sin ^{2} V_{\mathrm{x}}$. Nevertheless, given the magnitude of the coefficients in Equations 10 and 11, and the fact that $0^{\circ} \leq V_{\mathrm{x}} \leq$ $45^{\circ}$ so that $0 \leq \sin ^{2} V_{\mathrm{x}} \leq 0.5$, the relationship between $\Sigma \mathrm{t}_{1}$ and $\sin ^{2} V_{\mathrm{x}}$ is nearly linear. This explains why a linear regression performed on the data on Table 1, using $\sin ^{2} V_{x}$ as the independent variable and $\Sigma \mathrm{t}_{1}$ as the dependent variable, yields a coefficient of determination, $r^{2}=0.962$

Table 1. Potassium-rich alkali feldspars, their compositions (in mol $\% \mathrm{Or}$ ), $2 \mathrm{~V}_{\mathrm{x}}$ values and unit cell dimensions. For $2 \mathrm{~V}_{\mathrm{x}}$, a minus sign indicates that the optic axial plane is parallel to (010). Var = structural classification: MC = microcline, $\mathrm{OR}=$ orthoclase, $\mathrm{LS}=$ low sanidine, HS = high sanidine. As asterisk indicates the feldspar is metrically monoclinic, but topochemically triclinic. Ref = references, as listed at the bottom of the table.

standard deviations (esd) for the respective coefficients. Each indicates, as for the sigmoidal model, that if $V_{\mathrm{x}}$ equals $0^{\circ}$, then $\Sigma \mathrm{t}_{1}=0.665$ (esd $=0.02$ ). These equations predict that $2 V_{\mathrm{x}}$ will equal $57.6^{\circ}$ for a completely disordered high sanidine ( $\Sigma \mathrm{t}_{1}=0.5$ ) and $86.7^{\circ}$ for a completely ordered low microcline $\left(\Sigma t_{1}=1.0\right)$. These compare to literature values of $54^{\circ}$ and $82^{\circ}$. It should be noted that the largest $2 V_{\mathrm{x}}$ value reported for a sanidine, $63^{\circ}$, is for a
specimen synthesized by Tuttle (1952). Optically positive "isomicroclines" ( $2 V_{\mathrm{x}}>90^{\circ}$ ) were discussed in Footnote 2.

## Linear model: $\Sigma t_{1}$ versus $\tan ^{2} V_{x}$

Preiss (1981) and Ott (1982) found linear relationships for $\Sigma t_{1}$ or $t_{1}$ and $t_{2}$ versus $\tan ^{2} V_{x}$ for suites of monoclinic K -rich feldspars between $2 V_{\mathrm{x}} \sim 50^{\circ}$ [OAP $\left.=(010)\right]$ and

Fig. 4. $\operatorname{Sin}^{2} V_{\mathrm{x}}$ and $2 V_{\mathrm{x}}$ versus $\Sigma \mathrm{t}_{1}$; the $\Sigma \mathrm{t}_{1}$ values were determined by the [110],[ $\left.1 \overline{1} 0\right]$ method of Kroll (1980, as discussed by Kroll and Ribbe, 1983). The line represents a least-squares regression fit to the data for 52 specimens in Table 1. See Equations 12a and $b$, and $c f$. Su et al. (1983b) for an earlier version.
$2 V_{\mathrm{x}} \sim 63^{\circ}[\mathrm{OAP} \perp(010)]$. We tested $\tan ^{2} V_{\mathrm{x}}$ with our suite of 52 monoclinic and triclinic specimens and obtained an equation which may be split into two segments. For OAP $=(010)$,

$$
\begin{equation*}
\Sigma \mathrm{t}_{1}=0.664(4)-0.473(14) \tan ^{2} V_{\mathrm{x}} \tag{13a}
\end{equation*}
$$

and for $\mathrm{OAP} \perp$ or nearly $\perp$ to (010),

$$
\begin{equation*}
\Sigma t_{1}=0.664(4)+0.473(14) \tan ^{2} V_{x} \tag{13b}
\end{equation*}
$$

with $r^{2}=0.958$ and esd $=0.03$ (just slightly higher than the esd of 0.02 for equation 12).

The rationale for near-linearity in the relationship between $\Sigma \mathrm{t}_{1}$ and $\tan ^{2} V_{\mathrm{x}}$ is similar to that for $\Sigma \mathrm{t}_{1}$ and $\sin ^{2} V_{\mathrm{x}}$, because equations similar to 8 through 11 can be derived for the $\tan ^{2} V_{\mathrm{x}}$ function. The greater range of values of $\tan ^{2} V_{\mathrm{x}}$ (from 0.0 to 1.0 ) accounts for the smaller $r^{2}$ and larger esd for equation 13 over equation 12.

## Discussion and summary

## Earlier work and partial birefringences

Finney and Bailey (1964, Fig. 2, p. 426) plotted the distant order function.

$$
S=\sum_{i=1}^{i=4}\left[\frac{\left|0.25-t_{i}\right|}{1.50}\right]
$$

against $2 V_{\mathrm{x}}$ for all five structures of K-rich feldspars available at that time. Ribbe and Gibbs (1969, p. 86) recognized flaws in this and other distant order parameters and suggested that they be abandoned in favor of some more direct measure of the $\mathrm{Al} /(\mathrm{Al}+\mathrm{Si})$ content of the tetrahedral sites (for example, those used by Weitz (1972) and DePieri (1979)). But Finney and Bailey's result was nonetheless an important contribution.

As may be demonstrated mathematically, $S$ will be linearly related only to $\mathrm{t}_{1} \mathrm{o}$ when $\mathrm{t}_{1} \mathrm{~m}$ is $<0.25$, whereas, if $\mathrm{t}_{1} \mathrm{~m}>0.25$ or if the feldspar is monoclinic, S will be linearly related to $\Sigma t_{1}$. Of course, $\Sigma t_{1}$ is the parameter we find to be rather precisely predictable from $2 V_{x}$. Finney and Bailey (1964, Figs. 3 and 4) obtained a good nonlinear correlation of $2 V_{\mathrm{x}}$ and " b "- $\alpha$ and a nearly perfect linear correlation of $S$ and " $b$ "- $\alpha$, where the birefringence value " $b$ " $-\alpha$, as first proposed by Hewlett (1959), is equivalent to our ( $n_{\mathrm{b}}-n_{\mathrm{a}}$ ). Although they stated that their "diagrams should not be interpreted too vigorously . . . at this stage of our knowledge," Finney and Bailey's
ideas have proven to be correct. If we were to suggest a partial birefringence most sensitive to order-disorder in K-rich feldspars, it would be ( $n_{\mathrm{b}}-n_{\mathrm{c}}$ ), which passes through zero at $2 V_{\mathrm{x}}=0$. Values for a $\Sigma \mathrm{t}_{\mathrm{l}}$ versus ( $n_{\mathrm{b}}-n_{\mathrm{c}}$ ) plot may be derived from Figure 2.

## Complete characterization of Al,Si distribution in triclinic $K$-feldspar

A measurement of $2 V_{\mathrm{x}}$ (or partial birefringence, $\left(n_{\mathrm{b}}-\right.$ $\left.n_{c}\right)$ ) permits easy determination of $t_{1}$ or $\left(t_{1} \mathrm{o}+t_{1} m\right)$, and thus, using equation 3 , of $\mathrm{t}_{2}$ or $\mathrm{t}_{2} \mathrm{O}=\mathrm{t}_{2} \mathrm{~m}$. However, the individual Al contents of $\mathrm{T}_{1} \mathrm{O}$ and $\mathrm{T}_{1} \mathrm{~m}$ in triclinic potassic feldspars are not available from these measurements alone. Brown (1962, Fig. 2, p. 32) and Stewart (1974, Fig. 2, p. 158) suggested that the extinction angle $\alpha^{\prime}$ or $\mathrm{X}^{\prime}$ to the trace of ( 010 ) on (001) cleavage fragments may be linearly related to the difference $\left(\mathrm{t}_{1} \mathrm{O}-\mathrm{t}_{1} \mathrm{~m}\right)$. A few data suggest a correlation betwen this extinction angle and the $\gamma^{*}$ reciprocal lattice angle (Brown, 1962). In turn, $\gamma^{*}$ is well known to be linearly correlated to ( $\mathrm{t}_{1} \mathrm{O}-\mathrm{t}_{1} \mathrm{~m}$ ) (see Kroll and Ribbe, 1983, Fig. 5, p. 80). Marfunin (1966) hinted at the utility of angles between the individual optic axes and the normal to (010) in differentiating structural states of K-rich feldspars, but confirmation from lattice parameters or structure determination is lacking.

It is our intention to obtain complete optical and lattice parameter characterization of as many intermediate microclines as possible, so as to be able to fully characterize average $\mathrm{Al}, \mathrm{Si}$ site distributions in triclinic potassic feldspars using rapid spindle or universal stage methods.

## Unusual potassic feldspars

Bambauer and Laves (1960) studied a large ( $>1 \mathrm{~cm}$ ) adularia "crystal" from Val Casatscha, Switzerland. This specimen exhibited coarse lamellar domains whose $2 V_{\mathrm{x}}$ angles and $\alpha^{*}$ and $\gamma^{*}$ angles (recorded by X-ray precession methods) suggested a range of structural states from "(high) sanidine $\ldots$ (axial plane $\left.\sim \|(010), 2 V_{x} \simeq 50^{\circ}\right) \ldots$ to microcline $\ldots$ (axial plane $\sim \perp(010), 2 V_{x} \simeq 50^{\circ}$. Between these extremes a continuous series of intermediate optical orientations was found" (p. 178). These unusual orientations, representing a range of intermediate microclines with triclinic symmetry, are not accommodated by our model. Carefully correlated structural, optical, and electron microscope studies of these and similar specimens are now under way to resolve the discrepancies.

## Summary

Values of $2 V_{x}$ measured for potassic feldspars in thin sections, plus the observations of whether $r<v$, which indicates the optic plane to be parallel to (010), or $r>v$, which indicates the optic plane to be perpendicular to (010) or nearly so, should suffice to determine $t_{1}$ and $t_{2}$ (for monoclinic) or $\left(\mathrm{t}_{1} \mathrm{o}+\mathrm{t}_{1} \mathrm{~m}\right)$ and $\mathrm{t}_{2} \mathrm{O}=\mathrm{t}_{2} \mathrm{~m}$ (for triclinic crystals) from grain to grain (or point to point). Further
study is needed to confirm or establish more certainly the relationship between ( $\mathrm{t}_{1} \mathrm{O}-\mathrm{t}_{1} \mathrm{~m}$ ) and extinction angles, especially $\mathrm{X}^{\prime} \wedge(010)$ on (001), which has the greatest potential. The K-rich feldspars of "unusual" optic orientation require special attention.
We urge that all investigators measure and report full optical orientation data for crystals on which structures are determined or that investigators in possession of such crystals (or for that matter, any known intermediate microclines) send them to FDB or PHR for further study.

## Acknowledgments

The authors are grateful to numerous participants at the third NATO Advanced Study Institute on Feldspars and Feldspathoids for their stimulating discussions of this paper, especially Prof. H.-U. Bambauer. S. W. Bailey, Max Carman, and Elwood R. Brooks improved this paper with their reviews. This work was supported by National Science Foundation Grant EAR8018492 to F. D. Bloss and D. R. Wones and EAR-8308308 to F. D. Bloss and P. H. Ribbe.

[^1]:    ${ }^{2}$ Optically positive microclines ("iso-microclines') have been reported, but we have examined the specimens of Blasi (1972) by microprobe X-ray scanning methods and found them to be mechanical mixtures of exsolved low microcline $2 V x \approx 85^{\circ}$ ) and low albite ( $2 V_{x} \simeq 103^{\circ}$ ). For a detailed review of alkali feldspar optics, see Stewart and Ribbe (1983).
