#### Abstract

Werdingite, $\left(\mathrm{Mg}_{0.84}, \mathrm{Fe}_{0.16}\right)_{2} \mathrm{Al}_{12}\left(\mathrm{Al}_{0.79} \mathrm{Fe}_{0.21}\right)_{2} \mathrm{Si}_{4} \mathrm{~B}_{2}\left(\mathrm{~B}_{0.77} \mathrm{Al}_{0.23}\right)_{2} \mathrm{O}_{37}$, is a borosilicate mineral newly recorded from Namaqualand, South Africa, which has a structure based on chains of $\mathrm{AlO}_{6}$ octahedra parallel to c , cross-linked by $\mathrm{Si}_{2} \mathrm{O}_{7}$ groups, Al and Mg in five coordination, Al and Fe tetrahedra, and B triangles. It is triclinic $P \overline{\mathrm{I}}$, with $a=7.995(2), b=$ 8.152(1), $c=11.406(4) \AA, \alpha=110.45(2), \beta=110.85(2), \gamma=84.66(2)^{\circ}, V=650.5(3) \AA^{3}$, $Z=1$. The structure was solved by direct methods and refined to $R=0.044$ for 3584 reflections ( $I_{\text {rel }}>2 \sigma I_{\text {rel }}$ ) and 132 parameters. Although werdingite contains five-coordinated sites superficially similar to those in grandidierite and andalusite, the structure is best understood as being based on that of sillimanite, to which it is related by the overall substitution $2 \mathrm{~B}+(\mathrm{Mg}, \mathrm{Fe})=2 \mathrm{Si}+\mathrm{Al}+1.5(\mathrm{O})$ with local atomic displacements resulting from the loss of nonchain O atoms. The werdingite structure provides an explanation for the mechanism of B incorporation in sillimanite, which follows the same overall substitution, and sheds light on the nature of other mullite-like borosilicate phases encountered in experimental studies of the system $\mathrm{MgO}-\mathrm{Al}_{2} \mathrm{O}_{3}-\mathrm{B}_{2} \mathrm{O}_{3}-\mathrm{SiO}_{2}-\mathrm{H}_{2} \mathrm{O}$.

## Introduction

Werdingite is a borosilicate mineral recently described by Moore et al. (1990). It occurs in a high grade metamorphic rock associated with kornerupine, sillimanite, hercynite, grandidierite, and $\mathrm{Fe}-\mathrm{Ti}$ oxides at Bok se Puts, ( $30^{\circ} 7^{\prime} \mathrm{S}, 18^{\circ} 27^{\prime} \mathrm{E}$ ) in the granulite-facies region of the Na maqualand metamorphic complex, South Africa. Its powder diffraction pattern is similar to those of sillimanite, mullite, grandidierite, and related octahedral-chain aluminosilicates. Furthermore, synthesis experiments by Werding and Schreyer (1984) in the Al-rich part of the system $\mathrm{MgO}-\mathrm{Al}_{2} \mathrm{O}_{3}-\mathrm{B}_{2} \mathrm{O}_{3}-\mathrm{SiO}_{2}-\mathrm{H}_{2} \mathrm{O}$ have produced one or more unknown mullite-like phases with essential B and Mg , and G . Werding (personal communication) has recently succeeded in synthesizing the Mg-end-member $\mathrm{Mg}_{2} \mathrm{Al}_{14} \mathrm{~B}_{4} \mathrm{Si}_{4} \mathrm{O}_{37}$ in the anhydrous system. To shed light on the structural relationships of high- $T$ borosilicates, and on the possible nature of the B substitution recorded in some natural sillimanites (Grew and Hinthorne, 1983; Grew and Rossman, 1985), we have undertaken a structural study of natural werdingite from Namaqualand.
A clear, untwinned, inclusion-free fragment of werdingite was selected from a concentrate separated from the werdingite-bearing sillimanite-oxide rock, sample VP4. In this sample werdingite occurs as millimeter-sized crystals, commonly of short prismatic habit, with scattered inclusions of sillimanite. Many crystals show simple

[^0]twinning. Some are invaded by a grandidierite-spinel symplectite, and optical study shows that in many cases the $\mathbf{c}$ axes of werdingite and grandidierite approximately coincide. The mean composition of werdingite in this sample is given in Table 1.

## Experimental details

The unit cell was established as triclinic by the oscillation and Weissenberg methods, using $\mathrm{Cu} K \alpha$ radiation ( $\lambda=1.5418 \AA$ ). Accurate cell parameters were determined by a least-squares refinement of the setting angles of 24 reflections ( $16 \leq \theta \leq 17^{\circ}$ ) which were automatically located and centered on an Enraf-Nonius CAD4 diffractometer with graphite monochromated MoK $\alpha$ radiation ( $\lambda=0.7107 \AA$ ). The intensities were measured with an $\omega-2 \theta$ scan mode $\Delta \omega=(1.35+0.35 \tan \theta)^{\circ}$, an aperture width $(1.25+1.05 \tan \theta) \mathrm{mm}$ and a maximum recording time of 40 s . A total of 3724 unique reflections were measured out to $\theta=30^{\circ}$. The intensities of three reference reflections were monitored every hour, and orientation checked every hundred measured reflections. The data were processed for Lorentz and polarization factors and an empirical absorbtion correction (North et al., 1968) was applied. The observed and calculated structure factors are in Table 2. ${ }^{1}$ Further experimental details of the crystal and data measurement are reported in Table 3.

## Solution and refinement of the structure

For the solution and refinement of the structure 3584 reflections with $I_{\text {rel }}>2 \sigma\left(I_{\text {rei }}\right)$ were considered observed. The structure was initially solved in the noncentrosymmetric space group Pl using the direct-methods program SHELXS-86 (Sheldrick, 1987), which afforded the location of $\mathrm{Fe} / \mathrm{Mg}, \mathrm{Al}$, and Si atoms. Refinement of the structure was carried out with SHELX76 (Sheldrick, 1978). Observation of parameter correlation and centers of symmetry indicated $P \overline{1}$ as the preferred space group, and successful refinement of the structure with isotropic temperature factors in this system has vindicated its choice. Complex neutral atom scattering factors were taken from Cromer and Mann (1968), with dispersion corrections from Cromer and Liberman (1970). Molecular parameters were calculated using PARST (Nardelli, 1983). All computations were carried out using a VAX computer.

The unit cell has $Z=1$ and hence only half of the structure, i.e., $\left(\mathrm{Mg}, \mathrm{Fe}, \mathrm{Al}_{2}\right)_{2} \mathrm{Al}_{6} \mathrm{Si}_{2} \mathrm{~B}(\mathrm{~B}, \mathrm{Al}) \mathrm{O}_{18.5}$, had to be located. We distinguished between $\mathrm{Al}, \mathrm{Mg}$, and Si atoms by considering the number of and distance to adjacent $O$ atoms, and the shape of the polyhedron so described; Al has four (irregular tetrahedron), five (irregular trigonal

bipyramid), or six (irregular octahedron) O atoms, whereas Si has four O atoms defining a nearly regular tetrahedron. The Mg polyhedron is an irregular trigonal bipyramid, but its mean bond length of $1.985 \AA$ is distinctly longer than that of an adjacent Al trigonal bipyramid at $1.844 \AA$. For comparison, mean bond lengths for the Mg and Al chain-bridging trigonal bipyramidal sites in grandidierite are 2.042 and $1.838 \AA$, respectively (Stephenson and Moore, 1968).

Four Al atoms $\mathrm{Al}(5) 1, \mathrm{Al}(5) 2, \mathrm{Al}(6) 2$, and $\mathrm{Al}(6) 5$ were located in general positions. Four additional Al atoms $\mathrm{Al}(6) 1, \mathrm{Al}(6) 3, \mathrm{Al}(6) 4$, and $\mathrm{Al}(6) 6$ were located at centers of symmetry and assigned a site occupancy of 0.5 . The two Si atoms were located in general positions and underwent well-behaved refinement.

Part of the Fe was assigned to a tetrahedral site $\mathrm{Fe}(4) 1$, which showed the highest electron density. Since local charge balance indicates that this site should be occupied dominantly by trivalent cations, it was modeled by invoking partial occupancy by Fe and Al . Occupancy factors were refined with total occupancy 1.0 for the site, giving final occupancy values of $\mathrm{Fe} 0.21, \mathrm{Al} 0.79$. The

remaining Fe was assigned to the $\mathrm{Mg}(5) 1$ site, where a coupled refinement of Mg and Fe gave the final occupancy values $\mathrm{Fe} 0.16, \mathrm{Mg} 0.84$. The refinement thus indicates a total Fe content of 0.74 atoms per formula unit, compared with 0.86 from the chemical analysis.

Eighteen unique O atoms were located and refined satisfactorily. The remaining half-O atom, required by the stoichiometry from analytical results, is believed to be distributed between two sites O19A and O19B, each modeled with occupancy 0.25 .

One $B$ atom was assigned uniquely to site $B(3) 1$. The subsequent residual electron density was best modeled by again invoking disorder and partial site occupancy. The chemical analysis indicates a B content of less than four atoms per formula unit, and so 0.8 B and 0.2 Al were assigned and allowed coupled-occupancy refinement, with a total of $1.0(\mathrm{~B}+\mathrm{Al})$, at the sites $\mathrm{B}(3) 2$ and $\mathrm{Al}(4) 2$, respectively. The final occupancy values were B 0.77 , Al

Fig. 1. Plan view of part of the werdingite unit cell, projected down [001], showing the arrangement of octahedral $\mathrm{AlO}_{6}$ chains (dark shading) and double chains of bridging polyhedra (stippled). Vertical $\mathrm{BO}_{3}$ triangles shown as dark solid bars.
0.23 . This corresponds to a B content per cell of 3.54 , in excellent agreement with the chemical analysis.
The total Al content indicated by the refinement is 14.05 Al per cell, showing a small deficiency compared with the chemical analysis. We suggest that this is best described by a limited substitution in site $\mathrm{Mg}(5) 1$, in order to offset partially the excess Mg content of about 0.3 atoms which is implied by the refinement; regrettably we were unable to model this three-component site at $\mathrm{Mg}(5) 1$.

After the final refinement, the maximum residual electron density is located near $\mathrm{Al}(4) 1$ and no further improvement could be attained. The maximum and minimum residual densities are 1.72 and $-1.80 \mathrm{eA}^{-3}$, respectively. Fractional atomic coordinates and temperature factors for werdingite are reported in Table 4, bond lengths and angles in Table 5, and a summary of atomic sites and occupancies in Table 6.
A bond-valence analysis (Brown, 1981) was applied as a test of the site allocations in the refinement. The results, presented in Table 7, show that most sites are balanced with approximately integral charges except for the multiply occupied sites $\mathrm{Fe}(4) 1$ and $\mathrm{Mg}(5) 1$ and the partially occupied sites $\mathrm{B}(3) 2$ and $\mathrm{Al}(4) 2$. The charge balance indicates that the cations occupying $\mathrm{Fe}(4) 1$ should be about $70 \%$ trivalent, which in turn suggests that the Fe allocated to this site is dominantly divalent. $\mathrm{Mg}(5) 1$, on the other hand, would be balanced if it were $30 \%$ occupied by trivalent cations, some of which are presumably $\mathrm{Fe}^{3+}$ cations.

## Description of the structure

The unit cell of werdingite contains six octahedral aluminum sites, of which $\mathrm{Al}(6) 1, \mathrm{Al}(6) 3, \mathrm{Al}(6) 4$, and $\mathrm{Al}(6) 6$ lie on centers of symmetry, while $\mathrm{Al}(6) 2$ and $\mathrm{Al}(6) 5$ are

Fig. 2. Werdingite octahedral and polyhedral double chains, viewed normal to [001]. (a) Octahedral and polyhedral B-MgAl chains labeled A in Figure 1. (b) Octahedral and polyhedral $\mathrm{Al} / \mathrm{Fe}-\mathrm{Si}$ chains labeled B in Figure 1. Octahedral chains are viewed along the shared octahedral edges. Bridging chains are viewed normal to the plane containing the cations. $\mathrm{BO}_{3}$ triangles appear as dark solid bars.
on general positions. As shown in Figure 1, these Al polyhedra share edges to form two distinct chains running parallel to the c-axis, like those found in several other octahedral-chain aluminosilicates, such as sillimanite. Chain A (Fig. 2a) contains $\mathrm{Al}(6) 1, \mathrm{Al}(6) 2$ (linked by O 14 and O16) and $\mathrm{Al}(6) 3$ (linked by O 12 and O 15 ). Octahedral chain B (Fig. 2b) contains $\mathrm{Al}(6) 4, \mathrm{Al}(6) 5$ (linked by (O7 and O8) and $\mathrm{Al}(6) 6$ (linked by O 10 and O17). The c-axis repeat distance is equivalent to the height of four octahedral edges $(11.406 / 4=2.851 \AA)$. The octahedral Al-O distances are in the range $1.829(3)-1.979(3) \AA$, and the angles do not depart by more than $11^{\circ}$ from the ideal values of 90 and $180^{\circ}$ for the cis- and trans-O atoms respectively.

The two nonequivalent octahedral chains are linked by five-, four-, and three-coordinated cation sites (Fig. 2). The

Fig. 3. Two mullite-like constitutent slabs of the werdingite unit cell, each bounded by Al octahedra in the corner chains, and containing four of the 16 bridging cation sites. (a) $\mathrm{Al}_{2}$ [ MgAlBSi$] \mathrm{O}_{9}$ slab. (b) $\mathrm{Al}_{2}\left[\mathrm{Al}(\mathrm{Al}, \mathrm{Fe}) \mathrm{BSi}^{2} \mathrm{O}_{9.5}\right.$ slab. The long fifth bond to $\mathrm{Al}(5) 1$ is shown by a dashed line. In the adjacent slab to the right, B in $\mathrm{B}(3) 2$ has been replaced by Al in $\mathrm{Al}(4) 2$.
fivefold Al and Mg polyhedra may be described as irregular trigonal bipyramids. For the ideal trigonal bipyramid, one $\mathrm{O}-X$-O angle is $180^{\circ}$, three are $120^{\circ}$, and the remaining six are $90^{\circ}$. Corresponding angles for $\mathrm{Al}(5) 1$, $\mathrm{Al}(5) 2$, and $\mathrm{Mg}(5) 1$ are in the ranges $168.4(2)-175.4(2)^{\circ}$, 109.2(2)-123.2(2) ${ }^{\circ}$, and 74.3(2)-111.1(2) ${ }^{\circ}$, respectively. In each polyhedron, the cation lies out of the plane of the equatorial triangle, so that one bond is distinctly longer than the remaining four. The shorter bond ranges in length from 1.742 to $1.824 \AA$ for Al sites and from 1.901 to $1.973 \AA$ for the $\mathrm{Mg}(5) 1$ site. For $\mathrm{Al}(5) 2$ and $\mathrm{Mg}(5) 1$ the long bonds are 11 and $12 \%$ greater in length, respectively,

compared with $8 \%$ for the irregular five-coordinated Mg site in grandidierite. For $\mathrm{Al}(5) 1$, the fifth bond is $25 \%$ longer, and this site can be regarded alternatively as a tetrahedron.

The site $\mathrm{Fe} / \mathrm{Al}(4) 1$ is coordinated by three O atoms yielding metal-oxygen bond lengths of approximately $1.826 \AA$. The distances to a fourth disordered O atom, lying on one of the O19A or O19B sites, range from 1.648 to $2.062 \AA$, and the angles between the disordered and the well-behaved O atoms range from 91.0 to $144.0^{\circ}$. Si-O tetrahedral distances fall in the range 1.617(2)$1.650(2) \AA$, and $\mathrm{O}-\mathrm{Si}-\mathrm{O}$ angles, in the range $106.8-111.7^{\circ}$, are close to the ideal value for a regular tetrahedron. The $\mathrm{SiO}_{4}$ tetrahedra share an apex (O18) to form $\mathrm{Si}_{2} \mathrm{O}_{7}$ groups.

Both B sites are planar, almost equilateral triangles, with B-O distances of $1.360-1.427 \AA$.

Of the O sites, all but three are associated with the Al octahedral chains. The remainder, O1, O18, and O19A/ B, constituting five $O$ atoms per cell, link the polyhedra of bridging cations.

## DISCUSSION of The Structure and Comparison WITH GRANDIDIERITE AND SILLIMANITE

The occurrence of $\mathrm{Si}_{2} \mathrm{O}_{7}$ groups indicates that werdingite could be described as a disilicate. To do so, however, obscures the close relationship with other octahedral-chain aluminosilicates such as the $\mathrm{Al}_{2} \mathrm{SiO}_{5}$ polymorphs. The arrangement of $\mathrm{AlO}_{6}$ octahedral chains in werdingite is sim-

Fig. 5. Octahedral chain aluminosilicate structures related to werdingite. (A) View down [001] of lower half of the unit cell of grandidierite, after Stephenson and Moore (1968), reoriented for
ilar to those in sillimanite and grandidierite, and the principal differences among these minerals involve the bridging cation sites. It is convenient to consider the werdingite structure as composed of two slabs, flattened normal to c , of approximate dimensions $7.5 \times 7.6 \times 2.8 \AA$ (Fig. 3), which are stacked and inverted to make up the unit cell as shown in Figure 4. Each slab contains four of the 16 bridging cations, and the corners of the slab unit are defined by octahedral Al atoms in chain A . The slabs have dimensions similar to those of the unit cell of mullite. They are thus half the height of a sillimanite unit cell, and a representative unit of similar proportions can be formed from a quarter of a cell of the grandidierite structure (Fig. 5A).

A close structural relationship to the compositionally similar mineral grandidierite $\left(\mathrm{Al}_{2}\left[\mathrm{AlMgBSi}_{\mathrm{O}}^{9}\right.\right.$ ) might be expected. Indeed, slab 1 of the werdingite structure (Fig. 3a) shows some similarities in local configuration. Two of the nonchain O sites are vacant, and the approximate formula of the slab is $\mathrm{Al}_{2}\left[(\mathrm{Mg}, \mathrm{Fe}) \mathrm{AlBSi} \mathrm{O}_{9}\right.$. However, a comparison of Figures 3 and 5 shows that the superficial similarity indicated by the environment of B and the grouping of three bridging polyhedra does not extend to the longer-range configuration of bridging cations. In grandidierite, groupings of $\mathrm{Al}, \mathrm{Si}$, and Mg polyhedra alternate along $\mathbf{c}$ with large voids framed by $\mathrm{BO}_{3}$ triangles, but the double chains of bridging polyhedra characteristic of werdingite (Fig. 2a) are not present. The composition of slab 2 is $\mathrm{Al}_{2}[\mathrm{Al}(\mathrm{Al}, \mathrm{Fe})(\mathrm{B}, \mathrm{Al}) \mathrm{Si}] 0_{9.5}$, and here the bridging cations, except for $\mathrm{B}(3) 2$, are in near-tetrahedral coordination by anions.

The structure can alternatively be related to that of sillimanite, in which all the bridging cations are in tetrahedral coordination, with local rearrangements resulting from the removal of nonchain O atoms. A volume of sillimanite equivalent to that of the werdingite cell contains $\left.{ }^{[6]} \mathrm{Al}_{8}{ }^{[4]} \mathrm{Al}_{8} \mathrm{Si}_{8}\right] \mathrm{O}_{40}$, and thus three O atoms are missing from the werdingite structure. The double chains of alternating Al and Si tetrahedra parallel to the sillimanite c axis are replaced in the werdingite structure by the two types of polyhedral chains shown in Figure 2. The large voids produced by removing an O atom (equivalent to that in the $\mathrm{O}_{\mathrm{c}}$ site of sillimanite) are framed by pairs of $\mathrm{BO}_{3}$ triangles, or by displaced tetrahedral or five-coordinated sites, cross-linked to an adjacent polyhedral chain in a manner similar to that described for mullite in its
$\leftarrow$
comparison with werdingite slab 1 (Fig. 2a). Grandidierite cell outlined by dotted line. Dashed lines mark a subunit equivalent in shape to one layer of cations within the werdingite cell. (B) View down [001] of lower half of sillimanite unit cell. Atomic displacements resulting from the substitution $\mathrm{Al} \rightarrow \mathrm{Si}+0.5(\mathrm{O})$, as in mullite, shown by dashed lines. (C) Superimposed view down [001] of the cations of werdingite and sillimanite. Werdingite: cell outlined by solid line; cations are solid circles with radii $\mathrm{Fe} / \mathrm{Mg}>\mathrm{Al}=\mathrm{A} 1 / \mathrm{Fe}>\mathrm{Si}>\mathrm{B}$. Sillimanite: cell outlined by dashed line; cations are open circles with radii $\mathrm{Al}>\mathrm{Si}$.

Fig. 6. Two possible configurations of cation and $O$ site occupancy around the O19A and O19B sites in slab 2 of the werdingite structure, resulting from the substitution ${ }^{[4]} \mathrm{Al} \rightarrow{ }^{[3]} \mathrm{B}$, viewed down [001]. Two further configurations involving the upper O19A and O19B positions are symmetrically related to these.
relationship to sillimanite (Angel and Prewitt, 1986). Chain A shows a Si-Al ordering scheme opposite to that in sillimanite. The size difference between $\mathrm{Si}-\mathrm{Si}$ and $\mathrm{Al}-$ Al pairs is accommodated by a zigzagging of the $\mathrm{AlO}_{6}$ octahedral chains, which is in turn a consequence of the small $\mathrm{B}{ }^{[31} \mathrm{B}^{3+}$ cation pulling together alternate octahedral apices (Fig. 2a). The rotation of these Al octahedra is also responsible for bringing the larger bridging cations around O1 into five- rather than fourfold coordination.
The overall substitution relating werdingite to silli-
manite can be written $2 \mathrm{~B}+(\mathrm{Mg}, \mathrm{Fe})=2 \mathrm{Si}+\mathrm{Al}+1.5(\mathrm{O})$. This is identical to the substitution proposed for the accommodation of B in sillimanite with up to $0.42 \mathrm{wt} \%$ $\mathrm{B}_{2} \mathrm{O}_{3}$ by Grew and Hinthorne (1983) and Grew and Rossman (1985).
A notable feature of slab 2 of the werdingite structure is the positional disorder of O 19 , which is apparently distributed among four positions about the center of symmetry at $1 / 2,0,0$, between the cation sites $\mathrm{B}(3) 2, \mathrm{Al}(4) 2$, $\mathrm{Fe} / \mathrm{Al}(4) 1$, and their inverted equivalents in the adjacent cell. The idealized werdingite structure should have a single O atom at this special position. The chemical analysis and the refinement indicate that $\mathrm{B}(3) 2$ and $\mathrm{Al}(4) 2$ contain $77 \% \mathrm{~B}$ and $23 \% \mathrm{Al}$, respectively. Assuming that tetrahedral Al is bonded to O in O 19 A , the possible O configurations are likely to depend on the occupancy of neighboring $\mathrm{B}(3) 2$ and $\mathrm{Al}(4) 2$ sites, as shown in Figure 6. Furthermore, the four configurations should be equally represented when the Al occupancy is $33 \%$, which is not greatly different from the case in the natural sample. Clearly only one of the two possible adjacent $\mathrm{Al}(4) 2$ sites can adopt tetrahedral coordination with a single O19, and this is likely to place an upper limit of one atom per formula unit on the $\mathrm{Al}=\mathrm{B}$ substitution. It will be of interest to determine whether the O and cation disorder is random, or modulated. The effective size of the $\mathrm{Fe}(4) 1$ site and its distortion from tetrahedral symmetry are critically dependent on the position of the disordered O19, and the mean bond length ranges from 1.729 to $2.062 \AA$. The Fe cation is expected to prefer the largest configuration, in which Al occurs on one of the nearby $\mathrm{Al}(4) 2$ sites and is coordinated to an O atom in O19A. The refined occupancy of $\mathrm{Al}(4) 2$ implies that 0.23 of $\mathrm{Fe}(4) 1$ sites have long bonds to an O atom in O19A. The good match between this value and the refined Fe occupancy of $\mathrm{Fe}(4) 1$ $(0.21)$ suggests a possible coupling between the $\mathrm{Al} \rightarrow \mathrm{B}$ and $\mathrm{Fe} \rightarrow \mathrm{Al}$ substitutions in these two sites.

## Other structures related to werdingite

Sillimanite from certain high grade metamorphic rocks is known to contain up to $0.42 \% \mathrm{~B}_{2} \mathrm{O}_{3}$ (Grew and Hinthorne 1983). Sillimanite that is B rich also contains appreciable Mg , with an approximate cation ratio $\mathrm{B}: \mathrm{Mg}$ of 2:1. Grew and Rossman (1985) showed that B substitution in the small Si site caused a change from regular tetrahedral to trigonal or near-trigonal coordination, and they suggested that there are local rearrangements of nearby cation sites into configurations like that in grandidierite, so that the overall substitution is $2 \mathrm{~B}+\mathrm{Mg}=$ $2 \mathrm{Si}+\mathrm{Al}+1.5(\mathrm{O})$.

Grandidierite, however, has a B:Mg ratio of 1:1. The relationship between werdingite and sillimanite structures suggests that these rearrangements, rather than resembling the structure of grandidierite, correspond to parts of the werdingite structure, and a possible model for the substitution is shown in Figure 7. The presence of B in threefold coordination causes the loss of an O atom from

Fig. 7. A model for $\mathbf{B}$ substitution in sillimanite, in which an Al-Si tetrahedral double chain incorporates a werdingite-like section, with bridging O atoms $\mathrm{O}_{\mathrm{c}}$ removed. B triangles are viewed edgewise. Parentheses mark the positions of vacant $O$ sites, and underlined labels denote sites equivalent to those in werdingite (see Fig. 2a).
the $\mathrm{O}_{\mathrm{c}}$ site, and the Al coordinated to this $\mathrm{O}_{\mathrm{c}}$ site is presumed to be displaced into a mullite-like tetrahedral linkage to an adjacent polyhedral chain. To explain the incorporation of Mg , we propose that while the distortion caused by a single B substitution may not be sufficient to promote further rearrangement, the contraction resulting from two B atoms in alternate layers enlarges the intervening Al site so that occupation by the larger Mg cation is favored. The displacement toward the Mg site of an Al cation is accompanied by the loss of a third O atom from an adjacent polyhedral chain, and a small region resembling werdingite [but with Si taking the place of the neartetrahedral $\mathrm{Al}(5) 1]$ is produced (Fig. 7). An arrangement like this is presumed to be energetically more favorable than isolated or paired $\mathrm{B} \rightarrow \mathrm{Si}+0.5(\mathrm{O})$ substitutions.

Fig. 8. A possible structure for $\mathrm{Al}_{8}\left[\mathrm{Al}_{8}\left(\mathrm{~B}, \mathrm{Al}_{4}\right)_{4} \mathrm{Si}_{4}\right] \mathrm{O}_{38}$, the Mg free B-rich mullite of Werding and Schreyer (1984), based on repetitions of werdingite slab 2.

Other schemes of local B and Mg substitution are possible, leading to werdingite-like domains of different size. As with the model shown in Figure 7, charge balance across the boundaries of these domains, from which integral numbers of O atoms are missing, is not easily achieved unless coupled with further replacements in the sillimanite structure, of which the most likely is the mullite substitution $\mathrm{Al} \rightarrow \mathrm{Si}+0.5(\mathrm{O})$.

Sillimanite from the werdingite-bearing sample has 0.04 Mg atoms per formula unit of 20 O atoms, implying a B content of about double this value. This is comparable to the maximum B content of 0.08 B per $20(\mathrm{O})$ recorded in sillimanite from kornerupine-bearing rocks by Grew and Hinthorne (1983). A limit to the substitution may be set by the necessary rearrangements to adjacent bridging chains. In particular, the werdingite structure has an entirely different tetrahedral $\mathrm{Al}-\mathrm{Si}$ ordering scheme from that of sillimanite.

Further structural relationships are suggested by the products of synthesis studies in the system $\mathrm{MgO}-\mathrm{Al}_{2} \mathrm{O}_{3}{ }^{-}$ $\mathrm{B}_{2} \mathrm{O}_{3}-\mathrm{SiO}_{2}-\mathrm{H}_{2} \mathrm{O}$ by Werding and Schreyer (1984) and Werding (personal communication), which include new borosilicate phases with powder patterns resembling mullite. One of these is Al-rich, Mg-free B-rich mullite. A possible structure for this phase (Fig. 8) is based on repetitions of slab 2 of the werdingite structure, and has the overall ideal formula ${ }^{[6]} \mathrm{Al}_{8}\left[{ }^{[5]} \mathrm{Al}_{4}{ }^{[4]} \mathrm{Al}_{4} \mathrm{~B}_{4} \mathrm{Si}_{4}\right] \mathrm{O}_{38}$, with monoclinic symmetry $(C 2 / m)$. In addition, if the substitution ${ }^{[4]} \mathrm{Al} \rightarrow{ }^{[3]} \mathrm{B}$ occurs, as in werdingite (Fig. 6), that phase can show variable B content. Further substitutions of the type $\mathrm{B} \rightarrow \mathrm{Si}+0.5(\mathrm{O})$ in bridging polyhedral chain $B$ lead eventually to a Si-free end-member ${ }^{[6]} \mathrm{Al}_{8}\left[{ }^{[5]} \mathrm{Al}_{4}{ }^{[4]} \mathrm{Al}_{4} \mathrm{~B}_{8-x} \mathrm{Al}_{x}\right] \mathrm{O}_{36}$, which may have orthorhombic symmetry if the polyhedral chains are equivalent. Scholze (1956) synthesized orthorhombic phases of composition $2 \mathrm{Al}_{2} \mathrm{O}_{3}: \mathrm{B}_{2} \mathrm{O}_{3}$ and $9 \mathrm{Al}_{2} \mathrm{O}_{3}: 2 \mathrm{~B}_{2} \mathrm{O}_{3}$ at 1000 and 1100 ${ }^{\circ} \mathrm{C}$ respectively, with physical properties similar to those of mullite. The former corresponds to $x=0$ in the above formula. The phase of composition $9 \mathrm{Al}_{2} \mathrm{O}_{3}: 2 \mathrm{~B}_{2} \mathrm{O}_{3}$ shows solid solution with mullite, and when its formula is nor-
malized to 24 cations, it falls in the above solid solution range at $x=3.64$, near the probable limit of this ${ }^{[4]} \mathrm{Al} \rightarrow$ ${ }^{[3]} B$ substitution at $x=4$.

## Conclusions

The structure determination of werdingite has revealed a B-bearing member of a family of $\mathrm{AlO}_{6}$ octahedral chain structures based on sillimanite and mullite, and related by substitutions among the bridging cations, some of which involve the loss of nonchain O atoms (site $\mathrm{O}_{\mathrm{c}}$ of sillimanite). The most important of these substitutions appear to be $\mathrm{Al} \rightarrow \mathrm{Si}+0.5(\mathrm{O})$ (the mullite substitution) and $\mathrm{B} \rightarrow \mathrm{Si}+0.5(\mathrm{O})$, which is apparently coupled with $\mathrm{Mg} \rightarrow \mathrm{Al}+0.5(\mathrm{O})$ to derive the ideal magnesium werdingite structure, and which apparently also occurs in B-bearing sillimanite.

Internal substitutions within werdingite which may also occur in other members of the family include $\mathrm{Fe} \rightarrow \mathrm{Mg}$ in site $\mathrm{Mg}(5) 1$ and $\mathrm{Fe} \rightarrow \mathrm{Al}$ in site $\mathrm{Fe} / \mathrm{Al}(4) 1$ and $\mathrm{Al}(4) 2$ $\rightarrow \mathrm{B}(3) 2$. These last two substitutions may be coupled.

In werdingite the $\mathrm{AlO}_{6}$ octahedral chains are linked by $B$ triangles, whose small size causes a zigzag flexing of the chains. As a result there are different schemes of $\mathrm{Al}-\mathrm{Si}$ ordering in the bridging polyhedra: werdingite, and possibly also B-rich mullite, shows $\mathrm{Si}-\mathrm{Si}$ and $\mathrm{Al}-\mathrm{Al}$ pairs in contrast to the alternating $\mathrm{Si}-\mathrm{Al}$ tetrahedra in sillimanite. The same distortion of the octahedral chains causes some of the bridging cation sites to be five- rather than fourcoordinated, but despite this there is no long-range similarity to the cation arrangements in grandidierite and andalusite.
