# Four-membered rings in silica and aluminosilicate glasses 

Dan Sykes* and J.D. Kubicki ${ }^{\dagger}$<br>Division of Geological and Planetary Sciences, 170-25, California Institute of Technology, Pasadena, California 91125, U.S.A.

#### Abstract

Assignment of the peaks near $485 \mathrm{~cm}^{-1}$ in vibrational spectra of $\mathrm{SiO}_{2}-\mathrm{M}_{1 / n}^{n+} \mathrm{AlO}_{2}$ (where $\mathrm{M}=$ an alkali or alkaline earth element) glasses to $\nu_{s}(\mathrm{~T}-\mathrm{O}-\mathrm{T})$ modes in four-membered rings was tested with molecular orbital calculations. Potential energy minima of cyclic $\left(\mathrm{H}_{8} \mathrm{Si}_{m} \mathrm{Al}_{n} \mathrm{O}_{12}\right)^{n-}($ where $m+n=4), \mathrm{Li}_{2} \mathrm{H}_{8} \mathrm{Si}_{2} \mathrm{Al}_{2} \mathrm{O}_{12}, \mathrm{Mg}_{2} \mathrm{H}_{8} \mathrm{Al}_{4} \mathrm{O}_{12},\left(\mathrm{H}_{6} \mathrm{Si}_{2} \mathrm{AlO}_{9}\right)^{1-}$, and $\mathrm{LiH}_{6} \mathrm{Si}_{2} \mathrm{AlO}_{9}$ molecules were calculated. Force-constant analyses of the potential-energyminimized structures predict $\nu_{\mathrm{s}}$ (T-O-T) modes between 490 and $430 \mathrm{~cm}^{-1}$ depending on the number of Al atoms in the negatively charged four-membered rings and $\nu_{\mathrm{s}}(\mathrm{T}-\mathrm{O}-\mathrm{T})$ modes at 525 and $545 \mathrm{~cm}^{-1}$ in $\mathrm{Li}_{2} \mathrm{H}_{8} \mathrm{Si}_{2} \mathrm{Al}_{2} \mathrm{O}_{12}$ and $\mathrm{Mg}_{2} \mathrm{H}_{8} \mathrm{Al}_{4} \mathrm{O}_{12}$, respectively. The theoretical frequency shift of the $\nu_{s}(\mathrm{~T}-\mathrm{O}-\mathrm{T})$ mode calculated for the $\left(\mathrm{H}_{8} \mathrm{Si}_{m} \mathrm{Al}_{n} \mathrm{O}_{12}\right)^{n-}$ rings is consistent with the experimentally observed shifts of the peaks at 495-485 and 495-515 $\mathrm{cm}^{-1}$ in glasses along the $\mathrm{SiO}_{2}-\mathrm{NaAlSiO}_{4}$ and $\mathrm{SiO}_{2}-\mathrm{CaAl}_{2} \mathrm{Si}_{2} \mathrm{O}_{8}$ joins, respectively (McMillan et al. 1982; Seifert et al. 1982). Force-constant analyses of $\left(\mathrm{H}_{6} \mathrm{Si}_{2} \mathrm{AlO}_{9}\right)^{)^{--}}$and $\mathrm{LiH}_{6} \mathrm{Si}_{2} \mathrm{AlO}_{9}$ molecules predict a frequency of $573 \mathrm{~cm}^{-1}$ for the $\nu_{\mathrm{s}}(\mathrm{T}-\mathrm{O}-\mathrm{T})$ mode in both molecules, consistent with the assignment of peaks near $600 \mathrm{~cm}^{-1}$ in glasses along these joins to $\nu_{\mathrm{s}}$ (T-O-T) modes in three-membered rings (McKeown et al. 1984; Kubicki and Sykes 1993a). Intermediate-range order in $\mathrm{SiO}_{2}-\mathrm{M}_{1 / n}^{p+} \mathrm{AlO}_{2}$ glasses is interpreted in terms of changes in ring statistics. In $\mathrm{SiO}_{2}$, the Raman peaks at $606\left(\mathrm{D}_{2}\right), 495\left(\mathrm{D}_{1}\right)$, and 430 $\mathrm{cm}^{-1}$ correspond to three-, four-, and $>$ four-membered rings, respectively. The predominant low-frequency peaks in the vibrational spectra of glasses along the $\mathrm{SiO}_{2}-\mathrm{NaAlSiO}_{4}$ and $\mathrm{SiO}_{2}-\mathrm{CaAl}_{2} \mathrm{Si}_{2} \mathrm{O}_{8}$ joins at $540-606$ and $485-515 \mathrm{~cm}^{-1}$ are ascribed to three- and fourmembered rings, respectively.

## InTroduction

Structural models of fully polymerized silica, alkali aluminosilicate, and alkaline earth aluminosilicate glasses are commonly based on an interconnected network of corner-shared silicate and aluminate tetrahedra. However, there is little agreement on the nature of the inter-mediate-range structural features. Disagreement generally concerns the assignment of low-frequency bands in the vibrational spectra of aluminosilicate glasses (Bates et al. 1974; Sharma et al. 1978; McMillan et al. 1982; Seifert et al. 1982; Revesz and Walrafen 1983; Garofalini 1984; Sharma et al. 1985; Humbert et al. 1992). Silica glass has three low-frequency bands at 430, $495\left(\mathrm{D}_{1}\right)$, and $606\left(\mathrm{D}_{2}\right)$ $\mathrm{cm}^{-1} . D_{1}$ and $D_{2}$ have been interpreted as symmetric

[^0]stretching modes of Si-O-Si linkages in four- and threemembered rings of tetrahedra (Galeener et al. 1984; Barrio et al. 1993), broken Si-O bonds (Bates et al. 1974; Sharma et al. 1981; Humbert et al. 1992), and overcoordinated Si and O (Garofalini 1984). Along the $\mathrm{SiO}_{2}-$ $\mathrm{NaAlSiO}_{4}$ join, the frequencies of the bands at 495 and $606 \mathrm{~cm}^{-1}$ decrease to 485 and $560 \mathrm{~cm}^{-1}$ with the addition of $\mathrm{NaAlO}_{2}$. Simultaneously, the relative intensities of these bands increase up to the $\mathrm{NaAlSiO}_{4}$ composition (Seifert et al. 1982). McKeown et al. (1984) suggested that the 495 and $595 \mathrm{~cm}^{-1}$ bands in the spectra of $\mathrm{NaAlSi}_{3} \mathrm{O}_{8}$ glass correspond to the $D_{1}$ and $D_{2}$ "defect" bands in vitreous silica at 495 and $606 \mathrm{~cm}^{-1}$, respectively. Alternatively, McMillan et al. (1982) assigned the three low-frequency bands in glasses along this join to $\nu_{s}(\mathrm{Si}-\mathrm{O}-\mathrm{Si}), \nu_{\mathrm{s}}(\mathrm{Si}-\mathrm{O}-\mathrm{Al})$, and $\nu_{\mathrm{s}}$ (Al-O-Al) vibrational modes, respectively. Seifert et al. (1982) interpreted the Raman spectra of $\mathrm{SiO}_{2}{ }^{-}$ $\mathrm{M}_{1 / n}^{n+} \mathrm{AlO}_{2}$ glasses in terms of $\mathrm{Si}_{6}, \mathrm{Al}_{6}$, and $\mathrm{Si}_{2} \mathrm{Al}_{2}$ rings.

Kubicki and Sykes (1993a) tested Galeener and coworkers' (Galeener 1982a, 1982b; Galeener and Mikkelsen 1981; Galeener and Geissberger 1983; Galeener et al. 1984; Barrio et al. 1993) assignment of the $\mathrm{D}_{2}$ band in the Raman spectrum of silica to $\mathrm{O}_{\mathrm{br}}(\mathrm{O}$ atoms bonded to

two tetrahedral cations) "breathing" modes in threemembered silicate rings and found that molecular orbital calculations on cyclic $\mathrm{H}_{6} \mathrm{Si}_{3} \mathrm{O}_{9}$ accurately reproduce the frequency of the $D_{2}$ band in vitreous silica. Thus, the molecular orbital calculations for both $\mathrm{H}_{6} \mathrm{Si}_{3} \mathrm{O}_{9}$ and $\mathrm{H}_{6} \mathrm{Si}_{3} \mathrm{O}_{3}$ (O'Keeffe and Gibbs 1984) are consistent with assignment of the $\mathrm{D}_{2}$ band to breathing modes in threemembered rings. Because the frequencies calculated for $\mathrm{O}_{\mathrm{br}}$ breathing modes in aluminosilicate three-membered rings are in similar agreement with the observed vibrational spectra of sodium aluminosilicate glasses, Kubicki and Sykes (1993a) assigned the $540-600 \mathrm{~cm}^{-1}$ bands in the Raman spectra of the alkali and alkaline earth aluminosilicate glasses to $\mathrm{O}_{\mathrm{br}}$ breathing modes in threemembered aluminosilicate rings.

In this paper, we test the assignment of the 485-515 $\mathrm{cm}^{-1}$ peaks to $\mathrm{O}_{\mathrm{br}}$ breathing modes in four-membered rings of aluminate and silicate tetrahedra by comparing theoretical frequencies of cyclic $\left(\mathrm{H}_{8} \mathrm{Si}_{m} \mathrm{Al}_{n} \mathrm{O}_{12}\right)^{n-}$ molecules with the Raman spectra of silica and $\mathrm{SiO}_{2}-\mathrm{M}_{1 / n}^{n+} \mathrm{AlO}_{2}$ glasses. Similar models, based on the coupling of two four-membered rings to form the double four-mem-bered-ring structure D4R, are often used in the study of zeolite vibrational spectra (e.g., Creighton et al. 1994; Bartsch et al. 1994; Sauer and Hill 1994). Because $\nu_{s}$ (T-$\mathrm{O}-\mathrm{T}$ ) modes (i.e., the breathing mode in a regular ring structure) in zeolites with four-membered rings occur over the frequency range $486-521 \mathrm{~cm}^{-1}$ (Dutta et al. 1991), it is reasonable to expect that similar structures in glasses may produce frequencies in the same range. Furthermore, the anomalously narrow bandwidth of the $D_{1}$ peak in vitreous silica is evidence that a fairly regular structure causes this controversial peak (Galeener 1982a, 1982b). The nature of the small molecular rings can help constrain these species to fairly regular structural confor-
mations even in glasses. Hence, we modeled the inter-mediate-range structure of glasses with molecules comparable to the structures presumed to be present in the glasses.

## Methods

Minimum potential energy structures and vibrational modes of aluminosilicate rings were calculated using selfconsistent, Hartree-Fock molecular orbital calculations with $3-21 \mathrm{G}\left(^{*}\right)$ basis sets ( $\mathrm{G}=$ Gaussian functions, approximate Slater-type atomic orbitals; 3-21 $=3$ Gaussians per atomic orbital with the valence electrons represented with double-zeta Gaussians; * $=\mathrm{d}$ orbitals used as polarization functions on second-row atoms). Calculations were performed with the GAUSSIAN 92 program (Frisch et al. 1992). No symmetry constraints were placed on any of the molecules; $3 N-6$ (where $N=$ number of atoms) structural parameters of each molecule were allowed to vary independently to allow for full optimizations. For molecules with charge-balancing cations (i.e., $\mathrm{Li}^{+}$and $\mathrm{Mg}^{2+}$ ), the charge-balancing cations were initially placed in the center of the ring directly above or below the plane of the ring to allow the cation(s) to interact with the greatest possible number of $O$ atoms and to follow the most energetically favorable interactions. Stationary points were found to be true minima (although not necessarily global minima) of the molecular potential energy surface through force-constant analyses. All reported frequencies were scaled by 0.893 to correct for anharmonicity in the calculated harmonic frequencies, dissociation-limit errors in HF calculations, and the limitations of the $3-21 \mathrm{G}{ }^{*}$ ) basis set (Pople et al. 1981). Potential energies were corrected with zero-point energies (ZPE) determined in the force-constant analysis.

Figure 1．Minimum potential energy structure of Li－ $\mathrm{H}_{6} \mathrm{Si}_{2} \mathrm{AlO}_{9}$ from molecular orbital calculations with a $3-21 \mathrm{G}\left({ }^{*}\right)$ basis set．The $\nu_{\mathrm{s}}(\mathrm{T}-\mathrm{O}-\mathrm{T})$ mode at $574 \mathrm{~cm}^{-1}$ is an $\mathrm{O}_{\mathrm{br}}$ breathing mode similar to the $\nu_{s}(\mathrm{~T}-\mathrm{O}-\mathrm{T})$ modes of the other three－mem－ bered rings reported by Kubicki and Sykes（1993a）．Figure drawn with the program ATOMS（Dowty 1991）．

## Results

## Optimized structures

An optimized $\left(\mathrm{H}_{6} \mathrm{Si}_{2} \mathrm{AlO}_{9}\right)^{1-}$（hereafter denoted as $\mathrm{Si}_{2} \mathrm{Al}$ ） structure（Table 1）is similar to that reported by Kubicki and Sykes（1993a）for the partially optimized molecule． Thus，the structural trends discussed in that paper for the three－membered rings as a function of composition re－ main valid．The $\Delta E$ between the fully optimized $\mathrm{Si}_{2} \mathrm{Al}$ ring and that reported previously is only $-0.03 \mathrm{~kJ} / \mathrm{mol}$ before the ZPE correction is applied．The molecular structure of an $\mathrm{Li}^{+}$charge－balanced $\mathrm{Si}_{2} \mathrm{Al}$ ring is pictured in Figure 1．Addition of $\mathrm{Li}^{+}$to charge balance the mol－ ecule has little effect on the ring structure（Table 2）even though $\mathrm{Li}^{+}$forms bonds to three O atoms（Fig．1）．Av－ erage $\mathrm{Si}-\mathrm{O}, \mathrm{Al}-\mathrm{O}$ ，and $\mathrm{O}-\mathrm{H}$ bond distances are equal to within $<0.007 \AA$ between the negatively charged and neutral rings．Similarly，the calculated T－O－T and O－T－O angles（ $\mathrm{T}=\mathrm{Si}$ or Al ）agree to within $2^{\circ}$ between the two molecules．The average $\mathrm{Si}-\mathrm{O}-\mathrm{H}$ and $\mathrm{Al}-\mathrm{O}-\mathrm{H}$ angles in the $\mathrm{Li}^{+}$charge－balanced ring are $7-13^{\circ}$ larger than in the neg－ atively charged ring．

Structural parameters and potential energies（corrected for ZPE）of the fully optimized $(\mathrm{Si}, \mathrm{Al})_{4}$ rings are also giv－ en in Table 1．Calculated configurations of the $\left(\mathrm{H}_{8} \mathrm{Si}_{m} \mathrm{Al}_{n} \mathrm{O}_{12}\right)^{n-}$ molecules are nonplanar rings with one set of opposing T－O－T angles typically $138-148^{\circ}$ and the other set of opposing angles $127-139^{\circ}$ ．Both sets of in－ tertetrahedral angles are approximately $9^{\circ}$ smaller in the $\mathrm{Al}_{4}$ ring than in the $\mathrm{Si}_{4}$ ring． $\mathrm{T}-\mathrm{O}_{\mathrm{br}}$ bonds associated with

Table 2．Distances $(\AA \dot{A})$ ，angles $\left({ }^{\circ}\right)$ ，energies（Hartrees），and $\mathrm{O}_{\mathrm{br}}$ breathing－mode frequencies $\left(\mathrm{cm}^{-1}\right)$ of the charge－ balanced $\mathrm{Si}_{2} \mathrm{Al}$ and $(\mathrm{Si}, \mathrm{Al})_{4}$ aluminosilicate rings from molecular orbital calculations

Note：Numbers in angle brackets are average values．
the smaller set of T－O－T angles are longer by $\sim 0.02 \AA$ than the $\mathrm{T}-\mathrm{O}_{\mathrm{br}}$ bonds associated with the larger set of T－O－T angles．Average $\mathrm{Si}-\mathrm{O}_{\mathrm{br}}$ and $\mathrm{Al}-\mathrm{O}_{\mathrm{br}}$ bond lengths decrease with increasing Al content of the rings，whereas $\mathrm{Si}-\mathrm{O}_{n \mathrm{br}}$ and $\mathrm{Al}-\mathrm{O}_{n \mathrm{br}}$ distances increase（Table 1）．The av－ erage theoretical $\mathrm{Si}-\mathrm{O}_{\mathrm{br}}$ bond lengths of 1.614 and 1.609 $\AA$ for the $\mathrm{Si}_{3} \mathrm{Al}$ and the $\mathrm{Si}_{2} \mathrm{Al}_{2}$ rings，respectively，fall within the range of experimental $\mathrm{Si}-\mathrm{O}_{\mathrm{br}}$ bond lengths of 1.571 － $1.647 \AA$ recorded for natural albite $\left(\mathrm{NaAlSi}_{3} \mathrm{O}_{8}\right)$ and an－ orthite $\left(\mathrm{CaAl}_{2} \mathrm{Si}_{2} \mathrm{O}_{8}\right)$ mineral compositions（Wainwright and Starkey 1971；Kroll and Ribbe 1983）．Similarly，the calculated average $\mathrm{Al}-\mathrm{O}_{\mathrm{br}}$ bond lengths of $1.740 \AA$ in the $\mathrm{Si}_{2} \mathrm{Al}_{2}$ and $1.735 \AA$ in the $\mathrm{Al}_{4}$ rings fall within the range of experimental $\mathrm{Al}-\mathrm{O}_{\mathrm{br}}$ values of $1.698-1.779 \AA$ and 1．728－1．779 $\AA$ recorded for natural $\mathrm{CaAl}_{2} \mathrm{Si}_{2} \mathrm{O}_{8}$ and $\mathrm{CaAl}_{2} \mathrm{O}_{4}$ mineral compositions，respectively（Horkner and Muller－Buschbaum 1976；Kroll and Ribbe 1983；Muller et al．1986）．

Although all five rings optimized to nonplanar struc－ tures，bending the rings into planar geometries does not require a great deal of energy．Potential energies of $\mathrm{H}_{8} \mathrm{Si}_{4} \mathrm{O}_{12}$ and $\left(\mathrm{H}_{8} \mathrm{Si}_{2} \mathrm{Al}_{2} \mathrm{O}_{12}\right)^{2-}$ constrained to planar con－ figurations differ by only -4 and $+39 \mathrm{~kJ} / \mathrm{mol}$ from the nonplanar configurations．Note that the planar $\mathrm{Si}_{4}$ ring actually has a slightly lower potential energy than the nonplanar configuration after the ZPE correction has been made，even though the stationary－point energy of the pla－ nar configuration is $3 \mathrm{~kJ} / \mathrm{mol}$ higher than the nonplanar configuration（i．e．，the nonplanar ZPE is $7 \mathrm{~kJ} / \mathrm{mol}$ higher than the planar ZPE）．

Figure 2. Minimum potential energy structure of $\mathrm{Li}_{2} \mathrm{H}_{8} \mathrm{Si}_{2} \mathrm{Al}_{2} \mathrm{O}_{12}$ from molecular orbital calculations with a $3-21 \mathrm{G}\left(^{*}\right)$ basis set. The $\nu_{\mathrm{s}}(\mathrm{T}-\mathrm{O}-\mathrm{T})$ mode at $526 \mathrm{~cm}^{-1}$ is an $\mathrm{O}_{\mathrm{br}}$ breathing mode. The other four-membered rings in this study have similar structures, with bond lengths and angles listed in Tables 1 and 2. Each four-membered ring exhibits a similar vibrational mode. Figure drawn with the program ATOMS (Dowty 1991).

Calculated T-O bond distances of the OH-terminated molecules in this study are comparable to previous experimental (Glidewell et al. 1970) and theoretical (e.g., Chakoumakos et al. 1981; Casewit et al. 1992; Tossell 1993; Hill and Sauer 1994) studies of H-terminated fourmembered rings and the T-O bond distances found in crystalline silicates [see Ribbe (1983) for a review]. For example, the gas-phase molecule $\mathrm{H}_{8} \mathrm{Si}_{4} \mathrm{O}_{4}$ has average Si-O bond lengths of $1.628 \AA$ and $\mathrm{Si-O-Si}$ angles of $144.1^{\circ}$ (Glidewell et al. 1970) in comparison with 1.623 and $143.8^{\circ}$ calculated for our $\mathrm{Si}_{4}$ ring. Previous theoretical investigations have shown that T- $\mathrm{O}_{\mathrm{br}}$ bond lengths typically vary $<0.05 \AA$ as a function of molecular size (e.g., monomer, dimer, etc.), molecular composition (OH-vs. H-terminated), and basis set (e.g., Lasaga and Gibbs 1988; Nicholas et al. 1992). Therefore, the relative agreement between $\mathrm{T}-\mathrm{O}_{\mathrm{br}}$ bond lengths in the OH - and H -terminated $(\mathrm{Si}, \mathrm{Al})_{4}$ molecules is consistent with prior results.
Although T-O $\mathrm{O}_{\mathrm{br}}$ bond distances remain relatively constant between H - and OH -terminated molecules, calculated T-O-T bond angles depend on the type of terminal bond at this level of theory. In molecules of the type $\mathrm{H}_{3} \mathrm{~T}-$ $\mathrm{O}-\mathrm{TH}_{3}$, intertetrahedral angles of the optimized geometries are $180^{\circ}$ with $3-21 \mathrm{G}\left({ }^{*}\right)$ basis sets (Hill and Sauer 1989). On the other hand, in $(\mathrm{OH})_{3} \mathrm{~T}-\mathrm{O}-\mathrm{T}(\mathrm{OH})_{3}$ molecules, optimized T-O-T angles vary between 130 and $150^{\circ}$ (Geisinger et al. 1985; Sauer 1989; Nicholas et al. 1992; Kubicki and Sykes 1993b), a range that is more consistent with experimental values in crystals and glasses (Sharma et al. 1988; Geisinger et al. 1985). The above relationship is also observed in larger molecules of the type $\left(\mathrm{H}_{3} \mathrm{SiO}\right)_{3} \mathrm{TOH}$ and $\left[(\mathrm{OH})_{3} \mathrm{SiO}\right]_{3} \mathrm{TOH}$ (Kubicki and Sykes 1995). Tossell (1993) reported equilibrium bond angles of $\mathrm{Si}-\mathrm{O}-\mathrm{Si}=150^{\circ}, \mathrm{Si}-\mathrm{O}-\mathrm{Al}=155.9^{\circ}$, and $\mathrm{Al}-\mathrm{O}-\mathrm{Al}=151^{\circ}$

Figure 3. Minimum potential energy structure of $\mathrm{Mg}_{2} \mathrm{H}_{8} \mathrm{Al}_{4} \mathrm{O}_{12}$ from molecular orbital calculations with a 3-21G(*) basis set. The $\nu_{s}(\mathrm{~T}-\mathrm{O}-\mathrm{T})$ mode at $545 \mathrm{~cm}^{-1}$ is an O breathing mode, although the ring is highly distorted from a regular geometry in this case. Figure drawn with the program ATOMS (Dowty 1991).
for the cyclic molecules $\mathrm{H}_{8} \mathrm{Si}_{4} \mathrm{O}_{4}$, $\left(\mathrm{H}_{8} \mathrm{Si}_{2} \mathrm{Al}_{2} \mathrm{O}_{4}\right)^{2-}$, and $\left(\mathrm{H}_{8} \mathrm{Al}_{4} \mathrm{O}_{4}\right)^{4-}$, respectively. T-O-T angles calculated in the $\left(\mathrm{H}_{8} \mathrm{Si}_{m} \mathrm{Al}_{n} \mathrm{O}_{12}\right)^{n-}$ molecules are significantly lower (Table 1) and closer to experimental values. The frequencies predicted by Tossell (1993) for the symmetric stretching modes in the $(\mathrm{Si}, \mathrm{Al})_{4}$ rings differ from our own because of the different terminal bonds and T-O-T angles.

The inclusion of two $\mathrm{Li}^{+}$cations to charge balance the $\mathrm{Si}_{2} \mathrm{Al}_{2}$ ring (Fig. 2) significantly influences the optimized geometry of the molecule (Table 2). The average $\mathrm{Si}-\mathrm{O}_{\mathrm{br}}$ and $\mathrm{Al}-\mathrm{O}_{\mathrm{bc}}$ distances are larger by 0.017 and $0.032 \AA$, respectively, in the $\mathrm{Li}^{+}$charge-balanced molecule (Table 2). In contrast, T- $\mathrm{O}_{n \mathrm{br}}$ distances decrease by amounts almost equal to the observed changes in $\mathrm{T}-\mathrm{O}_{\mathrm{br}}$ bond lengths. The average Si-O-Al angle is identical in the two molecules, but the difference in the average T-O-T angle between the smaller set of opposing T-O-T angles ( $132.2^{\circ}$ ) and the larger set of opposing T-O-T angles (139.3 ) is smaller in the $\mathrm{Li}^{+}$charge-balanced ring than in the negatively charged ring ( 129.6 and $141.9^{\circ}$, respectively).

The addition of two $\mathrm{Mg}^{2+}$ cations to the $\mathrm{Al}_{4}$ ring $\left(\mathrm{Mg}_{2} \mathrm{H}_{8} \mathrm{Al}_{4} \mathrm{O}_{12} ;\right.$ Fig. 3) also results in significant changes in the ring structure compared with the negatively charged molecule. The average Al- $\mathrm{O}_{\mathrm{br}}$ distance increases by 0.034 $\AA$, whereas the average $\mathrm{Al}-\mathrm{O}_{n \mathrm{br}}$ distance decreases by 0.056 $\AA$ (Table 2). Al-O-Al intertetrahedral angles range from 133 to $173^{\circ}$, with the average angle ( $157^{\circ}$ ) approximately $23^{\circ}$ larger than in the $\mathrm{Al}_{4}$ ring. The addition of $\mathrm{Mg}^{2+}$ for charge balancing results in greater changes than the addition of $\mathrm{Li}^{+}$, and this is consistent with experimental and theoretical studies that suggest a larger effect of $\mathrm{Mg}^{2+}$
ions on aluminosilicate frameworks (Titova et al. 1995; Beran 1982).
However, the nature of the bonding between the aluminosilicate framework and either the $\mathrm{Li}^{+}$or $\mathrm{Mg}^{2+}$ chargebalancing cations is almost purely ionic. Natural bondorbital analysis (Glendening et al. 1992) reveals no bonds sharing electrons between the four-membered rings and the $\mathrm{Li}^{+}$or $\mathrm{Mg}^{2+}$. Only minor charge transfers occur from the T-O bonding and O lone-pair orbitals to the $\mathrm{Li}^{+}$and $\mathrm{Mg}^{2+}$ lone-pair antibonding orbitals. The largest decrease in charge computed for any O atom in these rings was only 0.1 e for a bridging O atom bonded to a $\mathrm{Mg}^{2+}$ ion in the $\mathrm{Al}_{4}$ ring. Hence, the nature and amount of this electron delocalization are similar to that calculated for hydrogen bonds in weakly interacting molecular complexes in which charge transfer from bonding to antibonding orbitals is thought to occur (Reed et al. 1988).

## Frequency analyses

Force-constant analysis of the $\mathrm{Si}_{2} \mathrm{Al}$ ring predicts a frequency of $573 \mathrm{~cm}^{-1}$ for the $\mathrm{O}_{\mathrm{br}}$ breathing mode, which is consistent with the predicted trend in Figure 4 derived from the other three-membered aluminosilicate rings (Kubicki and Sykes 1993a). The frequency of the $\mathrm{O}_{\mathrm{br}}$ breathing mode in the $\mathrm{Li}^{+}$charge-balanced $\mathrm{Si}_{2} \mathrm{Al}$ ring is also calculated to be $573 \mathrm{~cm}^{-1}$. These results are consistent with a weak interaction between the bridging O atoms and the low-field-strength charge-balancing cations (Roy and Navrotsky 1984) and with the premise that the $\mathrm{O}_{\mathrm{br}}$ breathing modes in the theoretical, non-charge-balanced, three-membered rings are representative of the $\mathrm{O}_{\mathrm{br}}$ breathing modes in the three-membered rings in the alkali aluminosilicate glasses (Kubicki and Sykes 1993a). This consistency is observed despite the fact that the Li-O interaction is stronger in the theoretical rings because the $\mathrm{Li}^{+}$cation in our optimized geometries is bonded to three O atoms rather than the four O atoms expected in the natural glass compositions on the basis of charge and mass-balance constraints. It might be expected, however, that the frequency of the $\mathrm{O}_{\mathrm{br}}$ breathing modes in threemembered rings with higher Li and Al contents could diverge from the trend defined by the sodic series in Figure 4 because of the higher field strength and lower coordination state of the $\mathrm{Li}^{+}$cation in comparison with that of the $\mathrm{Na}^{+}$cation in the aluminosilicate glass compositions.

Force-constant analyses of the optimized $(\mathrm{Si}, \mathrm{Al})_{4}$ ring geometries predict symmetric stretching modes of the bridging O atoms in each of the five molecules. The frequencies of these $\mathrm{O}_{\mathrm{br}}$ breathing modes range from 490 $\mathrm{cm}^{-1}$ in the $\mathrm{Si}_{4}$ ring to $430 \mathrm{~cm}^{-1}$ in the $\mathrm{Al}_{4}$ ring (Fig. 4). The predicted frequency of the $\mathrm{O}_{\mathrm{br}}$ breathing mode in the $\mathrm{Si}_{4}$ ring is within error of the $495 \mathrm{~cm}^{-1} \mathrm{D}_{1}$ band in silica glass. Furthermore, the ${ }^{18} \mathrm{O}-{ }^{16} \mathrm{O}$ frequency shifts of the breathing modes in the $\mathrm{Si}_{4}$ and $\mathrm{Si}_{2} \mathrm{Al}_{2}$ rings are -19 and $-23 \mathrm{~cm}^{-1}$, respectively. These values are similar to the

Figure 4. Frequencies of $O$ breathing modes calculated for three- and four-membered aluminosilicate rings as a function of $\mathrm{A} /(\mathrm{Al}+\mathrm{Si})$ ratio. Data represented by open circles and squares are frequencies of the $485-515$ and $540-606 \mathrm{~cm}^{-1}$ bands, respectively, in alkali aluminosilicate glass compositions (Seifert et al. 1982). Solid circles and squares are frequencies of the $O$ breathing modes for the theoretical three- and four-membered rings, respectively. Solid diamonds are frequencies of the O breathing modes for the $\mathrm{Li}^{+}$charge-balanced three- and fourmembered rings. The open diamond is the $\nu_{\mathrm{s}}(\mathrm{T}-\mathrm{O}-\mathrm{T})$ frequency for the $\mathbf{M g}^{2+}$ charge-balanced $\mathrm{Al}_{4}$ ring. Solid lines are best fits to theoretical points. The dashed lines represent experimental trends of the $\mathrm{D}_{1}$ and $\mathrm{D}_{2}$ peaks in $\mathrm{SiO}_{2}-\mathrm{CaAl}_{2} \mathrm{O}_{4}$ glasses.
measured value of $-30 \mathrm{~cm}^{-1}$ for the ${ }^{18} \mathrm{O}-{ }^{16} \mathrm{O}$ frequency shift of the $\mathrm{D}_{1}$ peak in silica glass (Galeener and Mikkelsen 1981). $\mathrm{Si}_{4}$ and $\mathrm{Si}_{2} \mathrm{Al}_{2}$ planar configurations have breathing-mode frequencies that are 16 and $7 \mathrm{~cm}^{-1}$ higher, respectively, than the nonplanar configurations. The correlations between predicted frequencies of $\mathrm{O}_{\mathrm{br}}$ breathing modes in $(\mathrm{Si}, \mathrm{Al})_{3}$ and $(\mathrm{Si}, \mathrm{Al})_{4}$ rings and the observed frequencies of the $540-606$ and $485-515 \mathrm{~cm}^{-1}$ peaks as a function of the $\mathrm{Al} /(\mathrm{Al}+\mathrm{Si})$ ratio of the ring or glass (Fig. 4) are evidence that these two bands in $\mathrm{SiO}_{2}-\mathrm{Na}-$ $\mathrm{AlSiO}_{4}$ glasses result from $\mathrm{O}_{\text {br }}$ breathing modes in threeand four-membered aluminosilicate rings.

The predicted frequencies of the $\mathrm{O}_{\mathrm{br}}$ breathing modes in the $\mathrm{Si}_{2} \mathrm{Al}_{2}$ and $\mathrm{Al}_{4}$ rings charge balanced by the $\mathrm{Li}^{+}$and $\mathrm{Mg}^{2+}$ cations are 525 and $545 \mathrm{~cm}^{-1}$, respectively. The frequencies are not consistent with the trend defined by the sodic series but do coincide with the trend for the calcic series (Fig. 4).

## DISCUSSION

Assignment of the $540-606 \mathrm{~cm}^{-1}$ peak to ( $\mathrm{Si}, \mathrm{Al}$ ) threemembered rings (Kubicki and Sykes 1993a) has important implications for the structural interpretation of aluminosilicate glasses. The observed (Sharma et al. 1978; McMillan et al. 1982; Seifert et al. 1982) and calculated decrease in the frequency of this band with increasing Al
content is evidence against $\nu_{s}$ (Si-O-Al) vibrations having a higher frequency than $\nu_{s}(\mathrm{Si}-\mathrm{O}-\mathrm{Si})$ vibrations. Because substitution of Al for Si tends to narrow T-O-T angles (Sharma et al. 1988) and closure of a given T-O-T angle shifts the $\nu_{\mathrm{s}}(\mathrm{T}-\mathrm{O}-\mathrm{T}$ ) vibration to higher frequencies (Furukawa et al. 1981; Kubicki and Sykes 1993b), some authors (e.g., McMillan et al. 1982) have assumed that the frequency of the $\nu_{\mathrm{s}}(\mathrm{T}-\mathrm{O}-\mathrm{T})$ vibrational mode would increase with Al content similarly to the observed pressuredependent shift of the $\nu_{\mathrm{s}}$ (T-O-T) vibrational mode with closure of the T-O-T angle in silica and aluminosilicate glasses (McMillan and Graham 1981; McMillan et al. 1984; Hemley et al. 1986). However, Kubicki and Sykes (1993b) noted that substitution of Al for Si in $(\mathrm{OH})_{3} \mathrm{~T}$ -$\mathrm{O}-\mathrm{T}(\mathrm{OH})_{3}$ molecules reduces the T-O-T angle, but the frequency of the $\nu_{s}(\mathrm{~T}-\mathrm{O}-\mathrm{T})$ symmetric stretch decreases because the $\mathrm{Al}-\mathrm{O}_{\mathrm{br}}$ bond is longer than the $\mathrm{Si}-\mathrm{O}_{\mathrm{br}}$ bond. Hence, the compositional effect is not equivalent to the pressure effect where the frequency of the symmetric stretch increases with closure of a given T-O-T linkage.
This same argument can be applied to the assignment of the $495-485 \mathrm{~cm}^{-1}$ peaks in alkali aluminosilicate glasses. The addition of $\mathrm{NaAlO}_{2}$ results in an observed overall increase in the frequency of the peak maximum of the dominant low-frequency peak from $430 \mathrm{~cm}^{-1}$ in $\mathrm{SiO}_{2}$ glass to $485 \mathrm{~cm}^{-1}$ in $\mathrm{NaAlSiO}_{4}$ glass (McMillan et al. 1982; Seifert et al. 1982). Previous interpretations (e.g., McMillan et al. 1982; Seifert et al. 1982) have attributed this behavior to an Si - and Al -dependent shift of the $\nu_{\mathrm{s}}(\mathrm{T}$ -$\mathrm{O}-\mathrm{T}$ ) vibrational mode at $430 \mathrm{~cm}^{-1}$ to higher frequencies [i.e., $\nu_{\mathrm{s}}(\mathrm{Si}-\mathrm{O}-\mathrm{Si}) \approx 430 \mathrm{~cm}^{-1} ; \nu_{\mathrm{s}}(\mathrm{Si}-\mathrm{O}-\mathrm{Al}) \approx 485 \mathrm{~cm}^{-1}$; $\left.\nu_{\mathrm{s}}(\mathrm{Al}-\mathrm{O}-\mathrm{Al}) \approx 560 \mathrm{~cm}^{-1}\right]$. Our results clearly demonstrate, however, that Al decreases the frequency of the $\nu_{s}(\mathrm{~T}-\mathrm{O}-\mathrm{T})$ vibration, and so the observed apparent increase in the principal low-frequency peak cannot simply be due to a frequency increase of the $\nu_{\mathrm{s}}(\mathrm{T}-\mathrm{O}-\mathrm{T})$ mode with substitution of $\mathrm{Al}^{3+}$ for $\mathrm{Si}^{4+}$.

Instead, the overall increase could be due to an increase in the percentage of four-membered rings and a decrease in the percentage of six-membered rings with increasing $\mathrm{NaAlO}_{2}$ content of the glass. As the intensity of the band due to the four-membered-ring structural feature increases with $\mathrm{NaAlO}_{2}$ content, the apparent low-frequency peak maximum increases. This interpretation is consistent with the small decrease in frequency of the $\nu_{s}(\mathrm{~T}-\mathrm{O}-$ T) mode from $495 \mathrm{~cm}^{-1}$ in $\mathrm{SiO}_{2}$ to $485 \mathrm{~cm}^{-1}$ in $\mathrm{NaAl}-$ $\mathrm{SiO}_{4}$, with Al content in the four-membered rings up to an $\mathrm{Al} /(\mathrm{Al}+\mathrm{Si})$ ratio of 0.5 where $\mathrm{Si}_{2} \mathrm{Al}_{2}$ rings predominate.

The increase in frequency of the $\mathrm{D}_{1}$ peak in silica to $515 \mathrm{~cm}^{-1}$ in $\mathrm{CaAl}_{2} \mathrm{Si}_{2} \mathrm{O}_{8}$ is explicable in terms of several factors. First, bandwidths recorded for the alkaline earth aluminosilicates are typically much broader than those recorded for the alkali aluminosilicates. Therefore, the calculated small shift of the $495 \mathrm{~cm}^{-1}$ peak combined with the large frequency decrease and concomitant intensity increase of the $540-606 \mathrm{~cm}^{-1}$ shoulder could result
in an apparent positive shift in the $495 \mathrm{~cm}^{-1}$ peak from increased band overlap. In addition, mass balance (e.g., one $\mathrm{Ca}^{2+}$ charge balances two Al tetrahedra in Ca $\mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{8}$ ) imposes constraints on the extended geometry of the glass, which may favor a higher proportion of threemembered rings in the alkaline earth aluminosilicates and lead to increased band overlap. Furthermore, charge-balancing cations with high field strengths (e.g., $\mathrm{Ca}^{2+}$ ) interact more strongly with the bridging O in $\mathrm{Al}-\mathrm{O}-\mathrm{Si}$ linkages than low-field-strength cations (e.g., $\mathrm{Na}^{+}$). This polarization of the bridging O weakens the Al-O-Si linkage (Roy and Navrotsky 1984) and results in a smaller observed dependence of the frequency of the symmetric stretching mode on the Al content of the T-O-T linkage or ring (Sharma et al. 1988; Kubicki and Sykes 1993a). In other words, the frequency of the vibrational mode is a function of the Al content and the type of charge-balancing cation. Given the weak Al dependence of the frequency of the $\mathrm{O}_{\mathrm{br}}$ breathing mode in the $(\mathrm{Si}, \mathrm{Al})_{4}$ rings, the strong interaction between Ca and the bridging O may result in a small increase in the frequency of the vibrational mode as a function of the $\mathrm{CaAl}_{2} \mathrm{O}_{4}$ content.

As a test of this hypothesis, a force-constant analysis was performed on the $\mathrm{Mg}_{2} \mathrm{H}_{8} \mathrm{Al}_{4} \mathrm{O}_{12}$ molecule. The predicted frequency of the $\mathrm{O}_{\mathrm{br}}$ breathing mode is $545 \mathrm{~cm}^{-1}$. As is evident from Figure 4, the predicted frequency of the $\mathrm{Mg}_{2} \mathrm{H}_{8} \mathrm{Al}_{4} \mathrm{O}_{12} \nu_{\mathrm{s}}(\mathrm{T}-\mathrm{O}-\mathrm{T})$ mode is close to the dominant low-frequency peak near $540 \mathrm{~cm}^{-1}$ in $\mathrm{CaAl}_{2} \mathrm{O}_{4}$ glass. Consequently, both $\mathrm{Al}_{3}$ and $\mathrm{Al}_{4}$ rings may contribute to the $540 \mathrm{~cm}^{-1}$ peak in the calcium aluminate glass spectrum.

The calculated frequency of $\mathrm{Li}_{2} \mathrm{H}_{8} \mathrm{Si}_{2} \mathrm{Al}_{2} \mathrm{O}_{12}$ is equal to $525 \mathrm{~cm}^{-1}$, which is close to the value of $515 \mathrm{~cm}^{-1}$ for a glass with $\mathrm{CaAl}_{2} \mathrm{Si}_{2} \mathrm{O}_{8}$ composition. The similar values between the $\mathrm{Li}^{+}$charge-balanced $\mathrm{Si}_{2} \mathrm{Al}_{2}$ ring and the calcic series may not be altogether fortuitous. Because the field strength of the $\mathrm{Li}^{+}$cation is larger than that of $\mathrm{Na}^{+}$, it is expected that as the LiAl content of the four-membered rings increases the calculated trend in frequencies for the theoretical $\mathrm{Li}^{+}$charge-balanced rings would diverge from the trend defined by the $\mathrm{SiO}_{2}-\mathrm{NaAlSi} \mathrm{O}_{8}$ glasses. In addition, the $\mathrm{Li}^{+}$cations are bonded to three O atoms rather than four as in the glasses, which leads to a stronger perturbation of the T-O-T linkages. In any case, our results do show that the frequency of the $\mathrm{O}_{\mathrm{br}}$ breathing mode is a function of the type of charge-balancing cation (M) and the MAl content of the ring or glass.
