#### Abstract

Seventeen crystals of eudialyte (sensu lato) differing in provenance and showing a wide range of chemical compositions were chosen for crystal-structure analysis and electron-microprobe analysis, supplemented with thermogravimetric analysis, infrared analysis, Mössbauer and optical absorption spectroscopy on selected samples. The structure consists of layers of six-membered rings of $\left[M(1) \mathrm{O}_{6}\right]$ octahedra linked together by $\left[M(2) \mathrm{O}_{n}\right]$ polyhedra sandwiched between two pseudocentrosymmetrically related layers of three-membered and nine-membered silicate rings forming a $2: 1$ composite layer. The $2: 1$ composite layers are crosslinked by Zr in octahedral coordination and are related to one another in accordance with the rhombohedral symmetry. This open structure is filled with $\left[\mathrm{Na} \phi_{n}\right]$ polyhedra in which Na may have various coordinations. The silicate network is relatively uniform in composition. The Zr site usually has a small amount of $\mathrm{Ti} . \mathrm{M}(1)$ is normally occupied mostly by Ca ; the main substitutions are $\mathrm{Mn}, R E E$ and Y . In one crystal, more than $50 \% \mathrm{Ca}$ is replaced by Mn and $R E E$, resulting in an ordering in two distinct sites, $M$ (1a) $(\mathrm{Mn})$ and $M(1 \mathrm{~b})(\mathrm{Ca}+R E E)$, and the symmetry reduced to $R 3 . M(2)$ is either a four-fold Fe -dominated site, or a five-fold site, usually Mn-dominated. $M(3)$ and $\operatorname{Si}(7)$ are two central sites of the two crystallographically distinct nine-membered silicate rings, and related by the substitution ${ }^{[6]} M(3)+{ }^{[4]} \mathrm{Si}(7) \Leftrightarrow 2^{[4]} \mathrm{Si}(7) . M(3)$ is dominated by Nb (or W), and $\operatorname{Si}(7)$, by ( $\mathrm{Si}, \mathrm{Al}$ ). Na is present in five distinct sites (acentric eudialyte) of which the $N a(4)$ site is particularly prone to incorporation of heavy elements such as $R E E$ and Sr. The $O(19)$ site plays a key role in the structure, being the ligand shared by the $M(3), M(2,5)$ and $N a(4)$ sites. The degree of acentricity is strongly correlated with the chemical elements in specific atomic sites. Eudialyte sensu stricto represents the most centrosymmetric structure, $R \overline{3} m$. As substitutions such as $\mathrm{Si} \Rightarrow(\mathrm{Nb}, \mathrm{W}), \mathrm{Fe} \Rightarrow \mathrm{Mn},(\mathrm{Ca}, \mathrm{Na}) \Rightarrow(R E E, \mathrm{Sr})$ take place, the structures become more and more noncentrosymmetric, $R 3 m$. The $R 3$ eudialyte has an incongruously low $\mid E^{2}-1 I$ value as a result of merohedral twinning. A complete formula for eudialyte requires structural data. An acceptable empirical formula, $\mathrm{Na}_{15}[M(1)]_{6}[M(2)]_{3} \mathrm{Zr}_{3}[M(3)]\left(\mathrm{Si}_{25} \mathrm{O}_{73}\right)\left(\mathrm{O}, \mathrm{OH}, \mathrm{H}_{2} \mathrm{O}\right)_{3} X_{2}$, can be calculated on the basis of $29(\mathrm{Si}, \mathrm{Al}, \mathrm{Zr}, \mathrm{Ti}, \mathrm{Hf}, \mathrm{Nb}, \mathrm{W}, \mathrm{Ta})$ apfu $(Z$ $=3$ ).

Keywords: eudialyte, kentbrooksite, crystal chemistry, single-crystal X-ray diffraction, electron-microprobe data.

## Sommaire

Nous avons sélectionné dix-sept cristaux d'eudialyte (sensu lato) de provenances différentes et définissant un grand intervalle de compositions chimiques pour une étude de leur structure cristalline, leur composition étant établie par analyse avec une microsonde électronique, et avec apport de résultats d'analyses thermogravimétrique, dans l'infra-rouge, et spectroscopiques

[^0](Mössbaucr et absorption optique) sur certains de ces échantillons. La structure est faite de couches d'anneaux à six octaèdres $\left[M(1) \mathrm{O}_{6}\right]$ liés l'un à l'autre par des polyèdres $\left[M(2) \mathrm{O}_{n}\right]$; ces couches sont intercalées entre deux autres couches possédant une relation par pseudocentrosymétrie, faites d'anneaux à trois et à neuf tétraèdres de silicate, le tout formant une couche composée 2:1. Ces couches $2: 1$ sont liées transversalement par des octaèdres contenant le Zr et sont en relation l'une avec l'autre selon une symétrie rhomboédrique. Les interstices de cette structure ouverte sont occupés par des polyèdres [ $\mathrm{Na} \phi_{n}$ ] dans lesquels le Na fait preuve d'une variété de coordinences. La trame silicatée est relativement uniforme en composition. Le site Zr contient une faible proportion de Ti , en général. Le site $M(1)$ contient normalement le Ca ; les substitutions principales impliquent le Mn , les terres rares et l'yttrium. Dans un cristal, plus de $50 \%$ du Ca est remplacé par Mn et les terres rares, avec comme résultat une mise en ordre de ces cations sur deux sites distincts, $M(1 \mathrm{a})(\mathrm{Mn})$ et $M(1 \mathrm{~b})(\mathrm{Ca}+$ terres rares), et une réduction de la symétrie à celle du groupe spatial $R 3$. Le site $M(2)$ possède soit une coordinence quatre où le Fe est dominant, soit une coordinence cinq, en général où le Mn est dominant. Les sites $M(3)$ et $S i(7)$ sont situés au centre des deux anneaux à neuf tétraèdres, qui sont cristallographiquement distincts; l'occupation de ces sites est régie selon la substitution ${ }^{[6]} M(3)+{ }^{[4]} S i(7) \Leftrightarrow 2{ }^{[4]} S i(7)$. Le site $M(3)$ contient surtout le Nb (ou le W), et $S i(7$ ) contient ( $\mathrm{Si}, \mathrm{Al}$ ). Le Na occupe cinq sites distincts (eudialyte acentrique), parmi lesquels le site $N a(4)$ est particulièrement sujet à l'incorporation d'éléments lourds, tels les terres rares et le strontium. Le site $O(19)$ joue un rôle-clé dans la structure, étant partagé par les sites $M(3), M(2,5)$ et $N a(4)$. Le degré d'acentricité dépend fortement des occupants des divers sites. L'eudialyte sensu stricto représente la structure centrosymétrique, $R \overline{3} m$. A mesure que les substitutions telles $\mathrm{Si} \Rightarrow(\mathrm{Nb}, \mathrm{W}), \mathrm{Fe} \Rightarrow \mathrm{Mn},(\mathrm{Ca}, \mathrm{Na}) \Rightarrow$ (terres rares, Sr ) prennent de l'ampleur, la structure devient de plus en plus non centrosymétrique, $R 3 m$. L'eudialyte $R 3$ fait preuve d'une valeur anormalement faible de $\left|E^{2}-1\right|$ à cause d'un maclage méroédrique. Pour écrire une formule complète d'un échantillon, il est nécessaire d'avoir des données sur la structure. En revanche, on peut calculer une formule acceptable, $\mathrm{Na}_{15}[M(1)]_{6}[M(2)]_{3} \mathrm{Zr}_{3}[M(3)]\left(\mathrm{Si}_{25} \mathrm{O}_{73}\right)\left(\mathrm{O}, \mathrm{OH}, \mathrm{H}_{2} \mathrm{O}\right)_{3} X_{2}$, en supposant 29 atomes de ( $\mathrm{Si}, \mathrm{Al}, \mathrm{Zr}, \mathrm{Ti}, \mathrm{Hf}, \mathrm{Nb}, \mathrm{W}, \mathrm{Ta}$ ) par unité formulaire ( $Z=3$ ).

## Introduction

Minerals of the eudialyte group are Na-rich zirconosilicates with varying amounts of $\mathrm{Ca}, \mathrm{Fe}, \mathrm{Mn}$, rare-earth elements ( $R E E$ ), $\mathrm{Sr}, \mathrm{Nb}, \mathrm{K}, \mathrm{Y}$ and Ti . They occur characteristically in agpaitic nepheline syenites and their associated pegmatites; rarely, eudialyte is encountered in peralkaline granites.

Eudialyte was first described from Kangerdluarssuk, in the Ilímaussaq alkaline complex, South Greenland (Stromeyer 1819). Since then, a very large number of eudialyte samples have been analyzed from other localities. These display a wide variation that results from real compositional variations as well as from significant analytical errors inherent in some of the methods used.

Golyshev et al. (1971) and Giuseppetti et al. (1971) independently solved the basic structure of eudialyte and showed it to be a cyclosilicate with both nine- and threemembered rings of [ $\mathrm{SiO}_{4}$ ] tetrahedra. The former authors solved the structure in space group $R 3 m$, the latter in $R \overline{3} m$. Subsequent refinements of the structure, e.g., those by Rastsvetaeva \& Andrianov (1987), Rastsvetaeva \& Borutskii (1988), Rastsvetaeva et al. (1988, 1990), provided additional structural information on eudialytegroup phases of different compositions, all in $R 3 \mathrm{~m}$. Still, until recently, some aspects of the crystal chemistry of the group remained obscure. For example, the nature of the principal substitutions, the number of anions and the number of Si atoms per formula unit (apfu) were still associated with considerable uncertainty.

Johnsen \& Gault (1997) studied the chemical variation in the eudialyte group using results of electron-mi-
croprobe analyses performed under uniform conditions. They concluded that a solid-solution series exists between the classic type of eudialyte rich in $\mathrm{Si}, \mathrm{Ca}, \mathrm{Fe}$ and Cl , and compositions rich in Nb, REE, Mn and F , such as kentbrooksite (Johnsen et al. 1998). On the basis of electron- microprobe information alone, that study could only address certain problems concerning this complex group of minerals.

In the present work, we examine the crystal-chemical properties of eudialyte (sensu lato) samples specifically selected from the material of Johnsen \& Gault (1997). The study is based on single-crystal structurerefinement data (SREF) and subsequent electron-microprobe analysis of the crystals used for SREF to ensure maximum compatibility within datasets. For selected samples, we had sufficient material for thermogravimetric analysis (TGA), infrared spectroscopy (IR), optical absorption spectroscopy (OAS) and Mössbauer spectroscopy.

## Experimental Methods and Procedures

Table 1 lists the provenance of the seventeen samples used in this study. All samples come from different specimens except for sample 11 and 12 , which come from rim and core, respectively, of the same crystal. We attempted to cover the entire observed range of compositions of eudialyte-group minerals from samples analyzed by Johnsen \& Gault (1997). In particular, we were interested in variations in $\mathrm{Ca}, \mathrm{Mn}, R E E, \mathrm{Si}, \mathrm{Nb}$ and Na contents. We kept the experimental method uniform for all samples in order to minimize systematic errors; we

thus are able to make meaningful comparisons of the crystal chemistry of various members of this complex group of minerals.

## Electron-microprobe analysis

Chemical analyses were done in wavelength-dispersion (WD) mode on a JEOL 733 electron microprobe using Tracor Northern 5500 and 5600 automation. Data were reduced with a conventional ZAF routine in the Tracor Northern TASK series of programs. Johnsen \& Gault (1997) gave the experimental details. For each sample but one, the actual crystal used in the structure refinement was analyzed chemically. Only sample 7 was lost during transfer to a probe mount. Fortunately, this material from the Kipawa complex, is quite homogeneous, such that the composition of the remaining crystal fragment was used.

Standards used in the analyses were vlasovite ( $\mathrm{Na} K \alpha, \mathrm{Si} K \alpha, \mathrm{Zr} L \alpha, \mathrm{Hf} L \alpha$ ), rutile ( $\mathrm{Ti} K \alpha$ ), manganocolumbite ( $\mathrm{Nb} L \alpha$ ), $\mathrm{NiTa}_{2} \mathrm{O}_{6}(\mathrm{Ta} M \alpha), \mathrm{CoWO}_{4}(\mathrm{WM} \mathrm{\alpha})$, almandine ( $\mathrm{Fe} K \alpha, \mathrm{AlK} \mathrm{\alpha}$ ), yttrium iron garnet (YIG) ( $\mathrm{Y} L \alpha$ ), a set of synthetic $R E E$ phosphates ( $\mathrm{La} L \alpha, \mathrm{Ce} L \alpha$, $\mathrm{Nd} L \alpha, \operatorname{Gd} L \alpha, \operatorname{Dy} L \beta, \operatorname{Er} L \alpha, \mathrm{Yb} L \alpha, \operatorname{Pr} L \beta, \operatorname{Sm} L \alpha)$, tephroite ( $\mathrm{Mn} K \alpha$ ), diopside ( $\mathrm{Ca} K \alpha, \mathrm{Mg} K \alpha$ ), celestine ( $\mathrm{Sr} L \alpha)$ ), sanbornite ( $\mathrm{Ba} L \alpha$ ), sanidine ( $\mathrm{K} K \alpha$ ), marialite ( $\mathrm{C} 1 K \alpha$ ) and phlogopite ( $\mathrm{F} K \alpha$ ). Sought but not detected in any of the samples were $\mathrm{Eu}, \mathrm{Tb}, \mathrm{Tm}$ and Lu . A beam $20 \mu \mathrm{~m}$ in diameter was used with all samples. Eudialyte itself seems quite stable in the electron beam with respect to all elements, but the vlasovite standard exhibited problems with Na migration. From a series of decomposition curves, correction factors of 0.859 and 1.006 were derived to apply to the $\mathrm{wt} . \% \mathrm{Na}_{2} \mathrm{O}$ and $\mathrm{SiO}_{2}$,
respectively. The relative error associated with this correction factor is $1.4 \%$. With the vlasovite standard, it was found that the correction could be applied equally well to the wt. $\%$, or as is more normal, to the counts before ZAF calculations. Still, a consistent disparity between Na content derived from the electron-microprobe analyses and structure refinements persists, as discussed later. The chemical compositions are given in Table 2.

## Normalization of the formula unit

Formula calculation for eudialyte has always been problematic because of the wide variety of chemical substitutions, disorder within the crystal structure and site vacancies. On the basis of a large dataset of over 60 chemical analyses in Johnsen \& Gault (1997) and the initial crystal-structure refinement of Johnsen et al. (1998), it became evident that unless specific structural information was available, normalization of the analytical data was best done on the basis of 78 anions ( $\mathrm{O}, \mathrm{Cl}$, F), with $Z=3$ for the unit cell. In the present study, we have calculated the number of atoms per formula unit (apfu) on an individual basis using the number of anions inferred from SREF data. The apfu and the number of anions are given in Table 2.

## Collection of X-ray-diffraction data

Crystals were selected for crystallographic data on the basis of optical clarity. In all cases, crystals were ground to spheres ranging in diameter from 0.12 to 0.20 mm . Each crystal was mounted on a Siemens fully automated four-circle diffractometer operated at 50 kV and

${ }^{* 166}=R \overline{3} m ; 160=R 3 m ; 146=R 3$. ${ }^{* *}$ Number of reflections collected. ${ }^{* * *}$ Goof $=$ Goodness-of-fit on $F^{2}$

40 mA with graphite-monochromated $\mathrm{Mo} K \alpha$ radiation. A set of 25 to 30 reflections were used to center the crystal and refine the cell parameters. Assuming a noncentrosymmetric rhombohedral cell, one asymmetric unit of intensity data was collected (i.e., $+h+k \pm l$ ) up to $2 \theta=60^{\circ}$ using a $\theta: 2 \theta$ scan-mode, with scan speeds inversely proportional to intensity, varying from 4 to $29.3^{\circ}$ /minute. The data collection for each crystal consisted of approximately 3800 reflections with more than $85 \%$ observed (i.e., $F_{0}>4 \sigma F_{0}$ ). Information relevant to the data collection and structure determination is given in Table 3. For the ellipsoidal absorption correction, 10 to 14 intense diffraction-maxima in the range 12 to $60^{\circ} 2 \theta$ were chosen for $\Psi$ diffraction-vector scans after the method of North et al. (1968). The merging $R$ for the $\Psi$-scan dataset decreased from approximately $1.5 \%$ before the absorption correction to approximately $1.0 \%$ after the absorption correction. The excellent merging $R$-values attest to the near-spherical shape of the crystals. Reduction of the intensity data, and determination and initial refinement of the structure were done with the SHELXTL (Sheldrick 1990) package of computer programs. Structure-refinement data for all crystals are given in Table 3. A set of normalized struc-ture-factors, $E$, were calculated, and the $\left|E^{2}-1\right|$ statistic is listed in Table 3. It should be noted that there is a distinct trimodal grouping; centrosymmetric eudialyte $(R \overline{3} m)$ has $\left|E^{2}-1\right|$ values in the range 0.96 to 1.04 , the noncentrosymmetric eudialyte ( $R 3 m$ ) has $\left|E^{2}-1\right|$ values in the range 0.75 to 0.96 , and the noncentrosymmetric ( $R 3$ ) eudialyte has an $\left|E^{2}-1\right|$ of 0.70 (See below). The latter, an incongruously low value for $\left|E^{2}-1\right|$, is a result of merohedral twinning (Herbst-

Irmer \& Sheldrick 1998). A discussion on these statistics is given later in the Degree of acentricity section.

## Final strategy in the refinements

The final refinements were done with the SHELXL93 program (Sheldrick 1993). The strategy applied to all crystals during the final stages of the refinement was to keep all atomic coordinates except $\operatorname{Zr}(z)$ variable, and thus refinable, as well as all anisotropic-displacement factors for all sites (except a few disordered sites). For disordered sites with low occupancy, such as the $X$ sites and the extra $M(3)$ or $S i(7 \mathrm{a})$ sites, an isotropic displacement parameter was kept fixed. SHELXL-93 recommendations for the splitting of sites were followed in those cases where the refinements remained stable.

The site-occupancy factors (sof) were fixed to unity for $S i(1)-S i(6)$ and $O(1)-O(18)$, and generally refined for the other sites. Wherever initial refinements indicated a site accommodating essentially only one atomic species, this species was assigned to the site, and the sof refined without constraints. In cases where initial refinements showed that the site accommodates, to a significant degree, more than one atomic species, and that the site is fully occupied, the two dominant elements assigned to the site are refined by coupling the positional and anisotropic-displacement parameters allowing the proportion of each sof to vary. Where substantial amounts of two elements are present in one site and the site is not fully occupied [e.g., M(3) in sample 6], the two elements were assigned to the site in a ratio established by the electron-microprobe data, and the sof of one element was allowed to refine in the final stage.

TABLE 4. ATOMIC COORDINATES ( $\mathrm{x} 10^{4}$ ) AND ISOTROPIC DISPLACEMENT PARAMETERS ( $\AA^{2} \times 10^{3}$ ) FOR THREE EUDIALYTE SAMPLES IN SPACE GROUPS $R \overline{3} m$ (166), $R 3 m$ (160) AND $R 3$ (146)

Corrections refined for secondary isotropic extinction were found to be insignificant and hence were omitted. For the noncentrosymmetric samples, incorporation of a twin fraction according to merohedral twinning in the refinements resulted in slight improvements of the agreement indices for some crystals and were kept. In the case of sample 5, belonging to space group $R 3$, introduction of a twin operation corresponding to the lost mirror plane in $R 3 m$ resulted in a significant improvement in the refinement, as the $R$-index dropped from 0.107 to 0.032 .

Table 4 contains complete sets of the final positional and equivalent isotropic-displacement parameters for a representative example of each of the three space groups concerned. Tables 5 and 6 list the positional parameters
of the remaining samples in $R \overline{3} m$ and $R 3 m$, respectively. Selected interatomic distances for one crystal in each space group are given in Table 7. Anisotropic-displacement factors and observed and calculated structure-factors for all samples have been submitted to the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ontario K1A 0S2, Canada.

## Site-assignment procedure

Table 8 presents the site-scattering values of the refined cation sites expressed in terms of electrons per formula unit (epfu) and atoms per formula unit (apfu), along with bond-valence and valence sums. Table 9

$\phi$ ：unspecified anion．
gives the epfu numbers for the refined anion sites．The site－assignment procedure applied includes the follow－ ing steps：
（i）Calculation of the number of anions：Site－scat－ tering values（epfu）of the refined anion－sites are con－ verted to apfu．$O(19)$ and $O(20)$ are considered to contain oxygen only，whereas the $X$ sites accommodate $(\mathrm{Cl}, \mathrm{F})$ derived from electron－microprobe data，and $(\mathrm{OH})$ is added to total 2 apfu．The remaining epfu in $X$ sites are considered to be $\left(\mathrm{H}_{2} \mathrm{O}\right)$ ．The apfu from these sites are added to the 72 atoms of oxygen belonging to the silicate ring system，giving the total amount of anions that，together with the derived number of $(\mathrm{H})$ ，form the basis of a recalculation of electron－microprobe data to give the apfu shown in Table 2.
（ii）Knowing the epfu of the cation－sites and the numbers of these sites in the structural formula（ $N$ in Table 4），and assuming full occupancy，an apfu popula－ tion of each site can be assessed on the basis of elec－ tron－microprobe data and guided by calculations of bond－valence and valence sums（Table 8）．This proce－ dure is valid for fully ordered structures covering most of the acentric crystals，whereas it becomes problem－ atic in cases with extensive disorder．In crystals where the pseudocentrosymmetrically related sites $M(3)$ and $S i(7)$ are disordered to such an extent that they are best refined in $R \overline{3} m$ ，the scattering overlap precludes the de－ termination of which cation is bonded to which ligand． In such cases，bond－valence sums cannot be calculated， and an apfu population for $M(3)$ and $\operatorname{Si}(7)$ together is

* Parameters from Brese \& O'Keeffe (1991). ** Standard deviations in parentheses estimated from s.d. of the site occupancy factors.
$\S$ For disordered structures, bond-valence sum for these sites cannot be calculated; for detailed discussion, see text.
VS for $\mathrm{Na}(5)$ in $R \overline{3} m$ eudialytes are calculated with multiplicity as in $R 3 m$.
proposed based on the sum of epfu from both $M(3)$ and $\operatorname{Si}(7)$ and their satellite sites and assuming $N=2$. The overall excellent agreement between the apfu derived from electron-microprobe data (Table 2) and those derived from structure refinements (Table 8) clearly indicates that this procedure is valid.
(iii) Assessment of the site population for the partly vacant $M(2)$ sites is generally done by first allocating Fe to $M(2,4)$, and secondly to $M(2,5)$, then the same
procedure with Mn . All remaining Mn is allocated to $M(1)$.

## Thermogravimetric analysis

The thermogravimetric analysis (TGA) of two eudialyte samples, $8(10 \mathrm{mg})$ and $10(16 \mathrm{mg})$, was done using a Stanton Redcroft TGA-DTA system; dry argon was used as purge gas. In both samples, weight loss was below the detection limits of the instrument.

* not refined. $O(19 a)$ epfu for samples 1,10 and 12 are $4.5,5.6$ and 7.5 , respectively. $O(20 \mathrm{a})$ epfu for samples 11 and 17 are 4.9 and 2.1, respectively. e.s.d. for epfu's are: $O(19) 2-5 \% ; O(19 a) \sim 10 \%$;
$O(20) 4-6 \%$; $O(20 \mathrm{a}) \sim 15 \% ; X(1)$ and $X(2) 3-8 \%$.

## Infrared analysis

Infrared spectra of selected samples of eudialyte (5, 8,10 and 13) were obtained using a Bomem Michelson MB-120 Fourier-transform infrared spectrometer with a diamond-anvil cell microsampling-device (sample 13) or a Perkin Elmer 1000 Fourier-transform instrument (samples 5, 8 and 10). The dominant absorption bands $\left(\mathrm{cm}^{-1}\right)$ are: that of the $[\mathrm{OH}]$ stretching modes (broad 3440 and 3150 ); the $\left[\mathrm{H}_{2} \mathrm{O}\right.$ ] bending mode (weak peak at 1655 ); the $\left[\mathrm{SiO}_{4}\right]$ symmetric stretching mode (major band with peaks at 1040,980 and 940 ); the [ $\mathrm{SiO}_{4}$ ] bending modes (sharp peaks at 760, 710 and 660). A complete description of an IR spectrum for kentbrooksite (sample 13) is given in Johnsen et al. (1998). The primary purpose in obtaining several selected IR spectra was to evaluate the role of OH and $\mathrm{H}_{2} \mathrm{O}$ in eudialyte. From these data, it is evident that both the OH and $\mathrm{H}_{2} \mathrm{O}$ species exist in eudialyte, but the latter seems of minor importance, whereas the proportion of OH is significant in the samples tested.

## Mössbauer and optical absorption spectroscopy

Mössbauer and optical absorption spectroscopy were performed on five samples of eudialyte (s.l.) given in Johnsen \& Gault (1997), one of which is included in the present study as sample 10 (U. Hålenius, pers.
commun.). The general results of the Mössbauer spectroscopy, performed at room temperature, are very similar to those of Pol'shin et al. (1991) with the exception that no evidence is found for ferric iron $\left(\mathrm{Fe}^{3+}\right)$. Neither is there any evidence for $\mathrm{Mn}^{3+}$ or $\mathrm{Fe}^{3+}$ in the data obtained from the optical absorption spectra. These observations are in accordance with the findings of $\mathrm{Mn}^{2+}$ only in kentbrooksite (Johnsen et al. 1998).

## Topology of the Structure

The site nomenclature for the $R 3 m$ type of eudialyte adopted here is based on that of kentbrooksite (Johnsen et al. 1998), with minor modifications. The $F$ sites in kentbrooksite are relabeled as $X$ sites, which is more appropriate for sites accommodating $\mathrm{Cl}, \mathrm{OH}, \mathrm{H}_{2} \mathrm{O}$ and F, whereas $M 4$ is relabeled $\mathrm{Si}(7)$ since Si has proven to be the predominant element at the site. $M 2$ is changed to $M(2,5)$, and $M 2$ a, to $M(2,4)$, in order to incorporate the coordination number in the notation.

The center of symmetry in the $R \overline{3} m$ type of eudialyte reduces the number of distinct sites, and $\operatorname{Si}(2)$ becomes symmetry-equivalent to $\operatorname{Si}(1), \operatorname{Si}(4)$ to $\operatorname{Si}(3)$, whereas $O(4), O(5)$ and $O(6)$ become equivalent to $O(1), O(2)$ and $O(3)$, and $N a(2)$ and $N a(3)$ become equivalent to $N a(1)$ and $N a(4)$. The reduction of symmetry from $R 3 m$ to $R 3$ results in a doubling of every general site in $R 3 \mathrm{~m}$, i.e., $M(1)$ degenerates into $M(1 \mathrm{a})$ and $M(1 \mathrm{~b})$, etc. The full notation for members of all three space groups is given in Table 4.

## Overview of the structure

The most characteristic property of the eudialyte structure is the unique combination of three- and ninemembered rings of $\left[\mathrm{SiO}_{4}\right]$ tetrahedra (Golyshev et al. 1971, Giuseppetti et al. 1971). These $\left[\mathrm{Si}_{3} \mathrm{O}_{9}\right]^{6-}$ and $\left[\mathrm{Si}_{9} \mathrm{O}_{27}\right]^{18-}$ rings are arranged in layers perpendicular to [001], with the configuration shown in Figure 1. Two such layers, related by a center or a pseudocenter of symmetry, embrace a layer of discrete rings of six $\left[M(1) \mathrm{O}_{6}\right]$ octahedra linked together by $\left[M(2) \mathrm{O}_{n}\right]$ polyhedra forming a $2: 1$ composite layer. The $2: 1$ composite layers are cross-linked by Zr in octahedral coordination and related to one another in accordance with rhombohedral symmetry. This open structure is filled with $\left[\mathrm{Na} \phi_{\mathrm{n}}\right]$ polyhedra in which Na may have various coordinations.

In the stacking sequence of the $2: 1$ layers and the layers with $\left[\mathrm{ZrO}_{6}\right]$ octahedra, twelve levels can be recognized within the repeat distance of the $c$ cell dimension. Figures 2 and 3 give a simplified representation of these levels from one six-fold ring of $\left[M(1) \mathrm{O}_{6}\right]$ octahedra to the next ring, for an acentric and a centric eudialyte, respectively. Oblong cages exist along the triad axes, reaching from one constriction made by a [ $\left.\mathrm{Si}_{3} \mathrm{O}_{9}\right]^{6-}$ ring up through the layer sequence to the next constriction by a $\left[\mathrm{Si}_{3} \mathrm{O}_{9}\right]^{6-}$ ring, including nine of the

Fig. 1. The nets of three-fold and nine-fold silicate rings in eudialyte-group minerals seen along [001].
twelve levels. In these cages, the central level comprises a region surrounded by six $\left[\mathrm{ZrO}_{6}\right]$ octahedra (only four of them are shown in the figures), and on either side followed by (i) an intra $\left[\mathrm{Si}_{9} \mathrm{O}_{27}\right]^{18-}$ ring level, (ii) a level with a region surrounded by $\left[M(1) \mathrm{O}_{6}\right]$ and $\left[M(2) \mathrm{O}_{\mathrm{n}}\right]$ polyhedra, (iii) an inter $\left[\mathrm{Si}_{9} \mathrm{O}_{27}\right]^{18-}$ ring level, and (iv) a level with a region surrounded by three $\left[\mathrm{ZrO}_{6}\right]$ octahedra. Na is the dominant cation in the cavities at the levels of $\left[\mathrm{ZrO}_{6}\right]$ octahedra and in other cavities in or at the border of other levels. $\mathrm{Cl}, \mathrm{F}, \mathrm{OH}$ and $\mathrm{H}_{2} \mathrm{O}$ are accommodated in the inter $\left[\mathrm{Si}_{9} \mathrm{O}_{27}\right]^{18-}$ ring levels, whereas the central parts of the $\left[\mathrm{Si}_{9} \mathrm{O}_{27}\right]^{18-}$ rings offer space for a cation in tetrahedral or octahedral coordination. Which is present depends on the incorporation or not of $O(19)$ which, where present, is shared with the $\left[M(2) \mathrm{O}_{5}\right]$ polyhedra. This important phenomenon will be discussed in detail below.

## Description and Discussion of the Atomic Sites

## The Si in three-membered rings

The $\left[\mathrm{Si}_{3} \mathrm{O}_{9}\right]^{6-}$ rings are uniform building blocks in all eudialyte crystals. In $R 3 m$, they are composed of $S i(1)$ and $S i(2)$ with their respective ligands, all atoms having point symmetry $m$. As seen in Figure 4, the [ $\left.\mathrm{Si}_{3} \mathrm{O}_{9}\right]^{6-}$ rings are linked to the six-membered rings of $\left[M(1) \mathrm{O}_{6}\right]$ octahedra by sharing the three innermost atoms of oxygen on each side. Figure 5 illustrates the corresponding configuration in $R 3$, where all positions are reduced to general positions and where the mutual
angle of rotation between the two three-membered silicate rings is other than $180^{\circ}$. In $R \overline{3} m$, the $\operatorname{Si}(1)$ and $\operatorname{Si}(2)$ tetrahedra are related by a center of symmetry. The tilt of the $S i(1)$ and $S i(2)$ tetrahedra toward the $Z$-axis differs from each other in acentric examples of eudialyte, and the degree of tilt varies from sample to sample: the largest difference is seen in sample 5, the R3 eudialyte.

For all crystals, the $\mathrm{Si}-\mathrm{O}_{\text {non-bridging }}$ bond-lengths are $1.58-1.60 \AA$, whereas the $\mathrm{Si}-\mathrm{O}_{\text {bridging }}$ bond-lengths are $\sim 1.64 \AA$. These are the expected values for essentially Al-free tetrahedra. The bond-valence sum of $\operatorname{Si}(1)$ for all samples is $4.09(5)$. For the noncentrosymmetric samples, the bond-valence sum of $S i(2)$ is $4.07(6)$.

## The Si in nine-membered rings

When referring only to $R 3 m$ and $R 3$ types of eudialyte, the Si atoms involved in the $\left[\mathrm{Si}_{9} \mathrm{O}_{27}\right]^{18-}$ rings are labeled so that all Si atoms in one silicate layer are either odd-numbered or even-numbered. Thus in the layer including the three-membered $S i(1)$ ring, the ninemembered ring is composed of a set of three $\operatorname{Si}(3)$ tetrahedra $[S i(3)$ having point symmetry $m$ in $R 3 m]$ and a set of six $S i(5)$ tetrahedra, with $S i(5)$ in a general position. In the next silicate layer, the tetrahedra are correspondingly labeled $\operatorname{Si}(2), \operatorname{Si}(4)$ and $\operatorname{Si}(6)$ except in $R \overline{3} m$, where these are generated by the center of symmetry.

The shape of the $\left[\mathrm{Si}_{9} \mathrm{O}_{27}\right]^{18}$ rings varies by tilting and rotation of the individual tetrahedra. The most pronounced shifts are exemplified by rotation of the $S i(5)$ and $\operatorname{Si}(6)$ tetrahedra about [001] (or a direction close to

FIG. 2. A simplified polyhedral model of noncentrosymmetric, $R 3 m$ eudialyte (s.l.), viewed approximately along [210].

Fig. 3. A simplified polyhedral model of centrosymmetric, $R \overline{3} m$ eudialyte ( $s . s$.), viewed approximately along [210].

FIG. 4. A six-fold ring of $\left[M(1) \mathrm{O}_{6}\right]$ octahedra with attached $\left[\mathrm{SiO}_{4}\right]$ tetrahedra in a $R 3 m$ type of eudialyte viewed along [001].
[001]) and tilting of the $\operatorname{Si}(3)$ and $\operatorname{Si}(4)$ tetrahedra equivalent to a rotation about [100]. Thus, owing to such adjustments, the distances between the three innermost atoms of oxygen of the rings can be made to fit the face of a tetrahedron or a face of an octahedron. For example, the distance between the $O(9)$ atoms of oxygen belonging to the $\operatorname{Si}(3)$ tetrahedra is typically $2.65 \AA$, matching the edge of a $\left[\mathrm{NbO}_{6}\right]$ octahedron, whereas the similar distance $O(12)-O(12)$ is on the order of $2.52 \AA$, matching the edge of $\mathrm{a}\left[\mathrm{SiO}_{4}\right]$ tetrahedron.

The $\left[\mathrm{Si}_{9} \mathrm{O}_{27}\right]^{18-}$ ring with a tenth Si tetrahedron in the center can also be described as a $\left[\mathrm{Si}_{10} \mathrm{O}_{28}\right]^{16-}$ platform. We prefer to keep the ring terminology, which we consider more applicable in the discussion of the crystalchemical characteristics of this group of minerals.

In $R \overline{3} m$ structures, small maxima labeled $\operatorname{Si}(3 \mathrm{~s})$ are observed in some cases. They are produced because $S i(3)$ and $S i(4)$, which ideally are related by the center of symmetry, are not completely superimposed in all parts of the crystal, indicating that the centricity is im-
perfect. This misalignment results in domains within the structure. Although of very minor significance in general, these maxima have been included in the refinement.

As in the case of the three-membered silicate rings, all crystals have $\mathrm{Si}-\mathrm{O}_{\text {non-bridging }}$ bond-lengths in the range $1.58-1.60 \AA$, whereas $\mathrm{Si}-\mathrm{O}_{\text {bridging }}$ bond-lengths are $\sim 1.64 \AA$ for the nine-membered silicate rings. Again, these are the expected values for essentially Al-free tetrahedra. The only sample in the present selection with appreciable amounts of Al is sample 17 from the Burpala massif, with 0.82 Al , all of which has been allocated to $M(2,5)$ and $M(3) / S i(7)$. The bond-valence sums of $S i(3)$ and $S i(5)$ for all samples are $4.07(5)$ and 4.05(5), respectively.

## The Zr site

Zr is accommodated in a nearly regular octahedron interconnecting one three-membered and two ninemembered silicate rings in one layer with a correspond-

FIG. 5. A six-fold ring of alternating $\left[M(1 a) \mathrm{O}_{6}\right]$ and $\left[M(1 \mathrm{~b}) \mathrm{O}_{6}\right]$ octahedra with attached [ $\mathrm{SiO}_{4}$ ] tetrahedra in a $R 3$ type of eudialyte viewed along [001].
ing set of rings in the next layer. Consequently, all ligands in this octahedron are shared with Si atoms. The mean $\mathrm{Zr}-\mathrm{O}$ bond-length for all samples is 2.068 (7) $\AA$, but an anomaly is noted. Within the dataset, sixteen samples have a mean $\mathrm{Zr}-\mathrm{O}$ distance of $2.070(4) \AA$, and one sample (sample 9 from Varennes) is characterized by a significantly shorter $\mathrm{Zr}-\mathrm{O}$ distance, $2.046 \AA$. This exception is in accordance with a substantial substitution of Ti for Zr in this sample, in which the site is occupied with $2.50 \mathrm{Zr}+0.50 \mathrm{Ti}$ apfu (Table 8). Among the other samples, only those from the Gardiner complex (samples 10, 11 and 12) contain appreciable amounts of $\mathrm{Ti}(0.20-0.34 \mathrm{apfu})$ in this site. Niobium plays a subordinate role in the Zr site; the highest amount of Nb assigned is 0.11 apfu in sample 4. Hafnium never exceeds 0.05 apfu. As seen in Table 8, the bond-valence sum of the $Z r$ site is consistently about $4 \%$ higher than the corresponding sum of valences, an indication that the bondvalence parameter for Zr (Brese \& O'Keeffe 1991) is slightly too high for this type of structure.

Khomyakov et al. (1990) described alluaivite from the Lovozero complex as having a eudialyte structure in which Ti replaces Zr entirely in this site. Recently, another eudialyte-group mineral has been found in Lovozero in which Ti substitutes for approximately onehalf the Zr (A.P. Khomyakov, pers. commun.). In that case, the two ions order to occupy positions in every second layer, causing the $c$ cell dimension to double. The only sample in the present dataset with appreciable amounts of Ti, sample 9 from Varennes, does not show any sign of ordering of the Zr and Ti at the Zr site.

## The M(1) site

The $M(1)$ site is octahedrally coordinated and shares all O ligands with Si atoms. It occupies a special position with point symmetry 2 in space group $R \overline{3} m$, but a general position in space group $R 3 m$ (Fig. 4) and two general positions $M(1 \mathrm{a})$ and $M(1 \mathrm{~b})$ in space group $R 3$ (Fig. 5). Edge-sharing $\left[M(1) \mathrm{O}_{6}\right]$ octahedra form six-
membered rings that on both sides are connected to a central three-membered silicate ring and three ninemembered silicate rings.

Plotted in Figure 6a, for all samples, are the mean bond-lengths of the $\left[M(1) \mathrm{O}_{6}\right]$ octahedra versus the ratio $\mathrm{Ca} /(\mathrm{Ca}+\mathrm{Mn}+R E E+\mathrm{Y})$ in $M(1)$, an expression that incorporates the most important elements of the site. In all samples, the $\left[M(1) \mathrm{O}_{6}\right]$ octahedra are somewhat distorted. The degree of distortion is related to nature of
occupant, as shown in Figure 6 b, in which a distortion index, $\Delta=1 / 6 \sum^{6}{ }_{i=1}\left[\left(\mathbf{R}_{i}-\bar{R}\right) / \bar{R}\right]^{2}$ (Brown \& Shannon 1973), is plotted against the components described above. In this context, it should be noted that the correlation shown is relatively poor, owing to the fact that all elements involved, like most elements in eudialyte, occupy more than one site in the structure. In addition, the degree of distortion of the $\left[M(1) \mathrm{O}_{6}\right]$ octahedra is not only dependent on the nature of the occupant, but also

Fig. 6. The ratio $\mathrm{Ca} /(\mathrm{Ca}+R E E+\mathrm{Mn}+\mathrm{Y})$ in $M(1)$ plotted against the mean bond-length of the $\left[M(1) \mathrm{O}_{6}\right]$ octahedron (a) and the distortion index of the $\left[M(1) \mathrm{O}_{6}\right]$ octahedron (b). The distortion index $\Delta$ is equal to $1 / 6 \Sigma^{6}{ }_{i=1}\left[\left(\mathrm{R}_{i}-\bar{R}\right) / \bar{R}\right]^{2}$ (Brown \& Shannon 1973). The symbols chosen are as in Table 1.
is influenced by the geometry of the surrounding structural blocks as well as by the different constraints on symmetry imposed in the three space groups concerned.

In most samples, Ca is the dominant element in $M(1)$, and in centrosymmetric eudialyte, it is the only significant element. The average Ca content in $M(1)$ is 4.69 apfu. Mn is next in importance with an average of 0.79 apfu, followed by REE and Y with $\sim 0.24$ apfu each. In sample 13 (labeled A in Fig. 6), almost half the Ca is substituted by $\mathrm{Mn}, \mathrm{Y}$ and REE in $M(1)$. This appears to be close to the limit where Ca and Mn order in two crystallographically distinct sites, as seen in sample 5. Ordering results in a distorted, Mn -dominant $\left[\mathrm{M}(\mathrm{la}) \mathrm{O}_{6}\right.$ ] octahedron, with a relatively small mean bond-length of $2.227 \AA$, and a less distorted, Ca - and $R E E$-dominant [ $M(1 \mathrm{~b}) \mathrm{O}_{6}$ ] octahedron, with a relatively large mean bond-length of $2.431 \AA$. As illustrated in Figure 5, the result is a loss of the mirror planes in $R 3 \mathrm{~m}$, and the symmetry thus is reduced to $R 3$.

The highest content of Y is found in samples 7 and 8 from the Kipawa complex, and all the Y is accommodated in $M(1)$. A small part of Fe ( 0.25 apfu ) in sample 15 from the Ilímaussaq complex is allocated to $M(1)$, and $0.66 a p f u \mathrm{Na}$ is assigned to the large $\left[M(1 \mathrm{~b}) \mathrm{O}_{6}\right]$ octahedron in sample 5. The iterative process of assigning several elements to several sites resulted, in the case of sample 9 from Varennes, in a small amount of Zr (0.18 apfu) being assigned to $M(1)$. In this particular case, the assignment appears insubstantial. It is maintained, however, because another crystal from the same locality, although excluded from the selection presented here owing to poor refinement results, shows an extremely high site-scattering value at the $M(1)$ site, which could only be attributed to a population including some Zr .

## The M(2) sites

The $M(2)$ notation includes two sites, the four-foldcoordinated $M(2,4)$ site and the five-fold-coordinated $M(2,5)$ site. The distance between these sites is on the order of $0.7 \AA$. They are positioned on the mirror plane, except in $R 3$, and bridge the six-membered rings of [ $M(1) \mathrm{O}_{6}$ ] octahedra. The $M(2,4)$ site is located on a center line between the six-membered rings on a position that in $R \overline{3} m$ has point symmetry $2 / m$, whereas the $M(2,5)$ site is shifted toward the $M(3)$ site (Figs. 2, 3).

The four-fold coordination of $M(2,4)$ is an almost planar arrangement with mean bond-lengths of 2.11 ( 6 ) and 2.09(4) for $M(2,4)-O(14)$ and $M(2,4)-O(17)$, respectively. Golyshev et al. (1971) and Giuseppetti et al. (1971) both assigned Fe to this site and made reference to gillespite (Pabst 1943), in which this unusual type of coordination was first observed. The $\mathrm{Fe}-\mathrm{O}$ distances in gillespite are $\sim 2.00 \AA$, i.e., slightly smaller than in eudialyte. In the present samples, Fe is assigned to $M(2,4)$ as well, and Mn subsequently, both elements as divalent ions in accordance with the results of the se-
lected tests for valence mentioned in the Methods section.

As seen in Table 8, the bond-valence sums (BVS) for $M(2,4)$ are consistently lower than the corresponding valence-sums (VS), on average $\sim 25 \%$ (this discrepancy would be even larger if trivalent ions were assigned). This overall BVS-VS discrepancy indicates that Fe is relatively poorly bonded in $M(2,4)$, which is also supported by very strong anisotropic displacement factors perpendicular to the plane of the oxygen atoms.

The five-fold coordination of $M(2,5)$ constitutes a distorted square pyramid involving the two pairs of $O(14)$ and $O(17)$ plus the extra $O(19)$; the mean bondlengths are as follows: $M(2,5)-O(14) 2.12(3), M(2,5)-$ $O(17) 2.20(9)$, and $M(2,5)-O(19) 2.1(2) \AA$. The $O(19)$ site has the same point symmetry as $M(2,5)$, and it constitutes the shared ligand between the $\left[M(2,5) \mathrm{O}_{5}\right]$ and [ $\left.M(3) \mathrm{O}_{6}\right]$ polyhedra. Not considering the $X$ sites, $O(19)$ is thus the only atom of oxygen in the eudialyte structure not bonded to Si . The anisotropic displacement parameters for $M(2,5)$ are relatively small compared with those of $M(2,4)$.

Whereas Fe distinctly predominates in $M(2,4)$, Mn is in general more abundant than Fe in $M(2,5)$. On average, $M(2,5)$ accommodates 0.85 Mn apfu and 0.55 Fe apfu. The highest content of Mn is 1.97 apfu, in sample 13. Note that in the assignment procedure, it is commonly impossible to distinguish between Fe and Mn where both are present in ample amounts unless specific spectroscopic information is available. Such information was sought on selected samples, but owing to serious overlap conditions, no conclusive results have been obtained so far (U. Hålenius, pers. commun.).

As seen in Table 8, the bond-valence sums (BVS) for $M(2,5)$ are in general lower than the corresponding valence-sums (VS) by an average of $\sim 15 \%$, which is less than for $M(2,4)$.

The site-occupancy factors (sof) for $M(2,4)$ and $M(2,5)$ are strongly correlated, such that during the refinement, great care was exercised in order to give realistic sof values. Figure 7 shows the distribution of the epfu in the two sites. It is obvious that the population is divided in two: some samples, in which the scattering power is concentrated in $M(2,4)$, refine as the centric type, whereas samples of a second group, with most electrons concentrated in $M(2,5)$, refine as the acentric type (an exception is sample 9). The role of the $M(2)$ site in the question of the acentricity in eudialyte, as well as the relations to neighboring sites, is discussed in greater detail below.

The total number of atoms per formula unit occupying the two $M(2)$ sites is 3 ; as shown in Figure 7, only two samples (14 and 15) reach about 77 epfu, corresponding to full occupancy with ( $\mathrm{Fe}, \mathrm{Mn}$ ). We also note that among the present samples, none have less than 55.7 epfu, equivalent to $\sim 2$ apfu ( $\mathrm{Fe}, \mathrm{Mn}$ ). The observation that other elements enter the Fe site, partly or entirely, as an integral part of the structure indicates that Fe itself

Fig. 7. The site-scattering power at site $M(2,4)$ plotted against the site-scattering power at site $M(2,5)$. The symbols chosen are as in Table 1.
is not essential for the stability of the eudialyte structure, as had been claimed by Christophe-Michel-Lévy (1961) on the basis of hydrothermal syntheses of eudialyte.

The $M(2)$ site (or an equivalent site) in six-fold coordination as described by Rastsvetaeva et al. (1990) has not been observed in this selection of eudialyte samples. The samples that refined centrosymmetrically did indicate six-fold coordination because of doubling the multiplicity of the $O(19)$ site, but subsequent refinement in the acentric space-group showed that all the scattering power originated from the "acentric" $O(19)$ site with half the multiplicity.

## The $M(3)$ site in acentric crystals

In the nine ordered structures of eudialyte belonging to space groups $R 3 m$ and $R 3, M(3)$ is a well-defined octahedral site with point symmetry 3 m , and bonded to three $O$ (19) atoms and the three innermost atoms of oxygen of the nine-membered silicate ring having oddnumbered Si atoms (Fig. 8). The mean bond-lengths are $2.00(6)$ and $1.88(2) \AA$ for $M(3)-O(9)$ and $M(3)-O(19)$, respectively.

Nb is clearly the dominant element in $M(3)$, except in sample 6, where W dominates. The highest Nb content, 0.95 apfu, occurs in sample 16 , whereas the remaining samples show some degree of site vacancy. The average of the bond-valence sums and valence sums for the $M(3)$ population in acentric crystals seen in Table 8
are $4.0(6)$ and $3.9(6)$ respectively, which gives an excellent overall agreement.

The $\operatorname{Si}(7)$ site in acentric crystals
$S i(7)$ and $M(3)$ are pseudocentrosymmetrically related. $\operatorname{Si}(7)$ is a tetrahedral site with point symmetry $3 m$ bonded to $O(20)$, which also has point symmetry $3 m$, and the three innermost atoms of oxygen of the ninemembered silicate ring with even-numbered Si atoms (Fig. 8). The mean bond-lengths are 1.60(2) and $1.60(3)$ for $\operatorname{Si}(7)-O(12)$ and $\operatorname{Si}(7)-O(20)$, respectively. In some crystals, there is an alternative position about $1.2 \AA$ removed from $\operatorname{Si}(7)$, still on the three-fold axis and more distant from $O(20)$ (Fig. 8). This site, labeled $\operatorname{Si}(7 \mathrm{a})$, also is tetrahedrally coordinated, where one of the disordered $X$ sites is incorporated as an apical ligand. It simply represents a reversed tetrahedron with the same mean bondlengths. In the most ordered crystals, these two sites together have a site-scattering value that roughly corresponds to one Si apfu. In other crystals, incipient disorder of the $M(3)$ and $S i(7)$ sites impede the interpretation of the stereochemistry along the triad axes, although these crystals still refine best in the acentric spacegroups. Accordingly, for these crystals, assignment of a certain scattering power to a certain site becomes dubious.

## The $M(3)$ and $\operatorname{Si}(7)$ sites in centric crystals

As the disorder on the triad axes becomes more extensive and the stereochemical substitution ${ }^{[6]} M(3)+$ ${ }^{[4]} S i(7) \leftrightarrow 2{ }^{[4]} S i(7)$ proceeds to the right, the data will give a superior refinement as a centrosymmetric structure. In such crystals, the scattering overlap precludes a reliable interpretation of the local stereochemistry except, of course, in the ideal situation of a full $2^{[4]} \mathrm{Si}(7)$ substitution. Sample 9 is the closest we get to this situation among the present samples. It should be stressed, however, that other features elsewhere in the structure also exert an influence on the degree of acentricity.

The scattering overlap results in small additional maxima along or very close to the three-fold axes. These "sites" have been labeled $M(3 \mathrm{a})$ and $M(3 \mathrm{~b})$, and their position is indicated in Figure 8. Their limited significance in relation to the important $\operatorname{Si}(7)$ and $M(3)$ sites in the various crystals can be read from Table 8. In Table 8, the site-scattering value of all $\operatorname{Si}(7)$ and $M(3)$ sites including the small additional maxima has been added up and converted to 2 apfu.

Johnsen \& Gault (1997) showed that a strong negative correlation exists between the presence of Nb and Si. The present study documents that this correlation is the chemical expression of the stereochemical substitution: ${ }^{[6]} M(3)+{ }^{[4]} \operatorname{Si}(7) \leftrightarrow 2{ }^{[4]} \operatorname{Si}(7)$. On the basis of the site assignment in Table 8, this correlation can be further refined as shown in Figure 9. In this plot, the abscissa

Fig. 8. A ball-and-stick model of $\operatorname{Si}(7)$ and $M(3)$ sites surrounded by the three innermost [ $\mathrm{SiO}_{4}$ ] tetrahedra in the nine-membered rings.
represents the chemical content of $2^{[4]} \mathrm{Si}(7)$, which is the total amount of Si and Al minus the Si in the silicate ring system (24 apfu) and a correction for Al in $M(2,5)$. The component represented along the ordinate axis is somewhat more elaborate. Although Nb is primarily accommodated in $M(3)$, small amounts of this element are found in the Zr site. In addition, Ti may be present in both $Z r$ and $M(3)$, as well as in $M(2,5)$ in some cases. In order to compensate for these complications, the
chemical content of $M(3)$ is expressed as the sum of all elements assigned to $M(3)$ and $Z r$ minus 3 apfu contained in Zr site and a correction for ( $\mathrm{Ti}, \mathrm{Zr}$ ) assigned in $M(2,5)$ and $M(1)$. The corrections made are indicated on the plot with dashed lines. The coefficient of correlation after the corrections is $r=-0.96$.

The plot in Figure 9 and the incorporated corrections confirm that the result of the site-assignment procedure seen in Table 8 is reasonable. It also shows that there is

Fig. 9. The correlation between the occupancy of $M(3)$ and $\operatorname{Si}(7)$, both defined in text. The symbols chosen are as in Table 1. The dashed lines signify the following corrections made: sample $\mathrm{h}:-0.24 \mathrm{Zr}$ in $M(2,5)$; sample $\mathrm{A}:-0.14 \mathrm{Al}$ in $M(2,5)$; sample B: $-(0.42 \mathrm{Al}+0.24 \mathrm{Ti})$ in $M(2,5)$; sample $\mathrm{V}:-0.18 \mathrm{Zr}$ in $M(1)$ and -0.25 Ti in $M(2,5)$.
an excellent agreement overall between the apfu derived from structural calculations and those from the electronmicroprobe data. Most important, however, is the conclusion drawn from Figure 9 that the ${ }^{[6]} M(3)+{ }^{[4]} S i(7)$ $\leftrightarrow 2^{[4]} \operatorname{Si}(7)$ relation is substantiated, i.e., Nb , and sub-
stitutions, in $M(3)$ do not exceed 1 apfu. In other words, there is no indication in the present dataset that $M(3)$ can be found in both crystallographically distinct ninemembered silicate rings, yet the structural explanation for this finding is not clear. Two ${ }^{[6]} M(3)$ sites would require doubling of the multiplicity of $O(19)$ and a change of the coordination of $M(2)$ from five to six. The extra $O(19)$ atoms of oxygen can be accommodated in the cages, and the six-fold coordination of $M(2)$ has been observed (Rastsvetaeva et al. 1990). In addition, the rest of the eudialyte structure is already essentially centrosymmetric in nature. At present, we do not exclude the possible existence of two $M(3)$ sites.

## The Na sites

The structural framework hitherto described is saturated with Na ; its locations are indicated in Figures 2 and 3. In $R 3 m$ and $R 3$, five distinct $N a$ sites are recognized. In $R \overline{3} m$, these five are reduced to three as $N a(2)$ is included in $N a(1)$, and $N a(3)$ in $N a(4)$, whereas $N a(5)$ is unchanged except for the site-occupancy factor, which drops to one-half. Doubling the multiplicity of the $N a(5)$ site results in Na atoms being positioned closer than 2 $\AA$ apart. Valence sums for $R \overline{3} m$ eudialyte samples in Table 8 are therefore calculated on the basis of the same multiplicity for the site as in $R 3 m$.

All five $N a$ sites have point symmetry $m$ (except in $R 3$ ) and thus add up to 15 apfu. Some $N a$ sites, mainly $N a(1)$ and $N a(3)$, have such large anisotropic displace-ment-parameters within the mirror planes that they are best described as split positions.

Fig. 10. A ball-and-stick model of the $N a(4)$ site surrounded by selected polyhedra. Notice the strong disorder of the large $X$ anions and the sharing of $O(19)$ with the $\left[M(2,5) \mathrm{O}_{5}\right]$ and $\left[M(3) \mathrm{O}_{6}\right]$ polyhedra.

Selected mean bond-lengths for the $\left[\mathrm{Na} \phi_{n}\right]$ polyhedra ( $\phi$ : unspecified anion) are presented in Table 7. The coordination number of Na out to a distance of $3.10 \AA$ ranges from 6 to 10 , counting the disordered $X$ sites as one ordered site only. The $\left[\mathrm{Na} \phi_{n}\right]$ polyhedra are very irregular, and it is evident that Na simply must accept the space determined by the framework. In particular, Na is concentrated in the [110] channels running between silicate rings as well as between $\left[\mathrm{ZrO}_{6}\right]$ octahedra. It is probable that these channels constitute the paths through which Na may be leached out and exchanged for $\mathrm{H}_{2} \mathrm{O}$ or $\mathrm{H}_{3} \mathrm{O}^{+}$, as described by Rastsvetaeva et al. (1990). We also attempted to include a Na-poor eudialyte in this study, but we were unable to achieve an acceptable refinement of this particular crystal. Regardless of this, as mentioned in the section on microprobe analyses, Na volatilization or migration does not appear to be a major problem in eudialyte-group phases, indicating that Na generally bonds well within the structure. A different perspective on this matter might be extracted from the bond-valence sums and valence sums cited for the Na sites in Table 8. For $\mathrm{Na}(1), \mathrm{Na}(2), \mathrm{Na}(5)$ and in part $\mathrm{Na}(3)$, the VS values are $10-20 \%$ higher than the corresponding BVS values, indicating fairly weak bonding, whereas atoms in $N a(4)$ and in part $N a(3)$ seem more tightly bonded, judging from the better agreement between BVS and VS results.

With very few exceptions, Na is the only element in $N a(1), N a(2)$ and $N a(5)$. A small proportion of vacancies in $N a(5)$ is encountered in some crystals. Sites $N a(3)$ and $N a(4)$, on the other hand, do carry substantial amounts of other elements; in $N a(4)$ in particular, the site-scattering values may be high enough in some crystals that Na can no longer be the dominant element. For example, in sample 5, almost half of the site population in $N a(4)$ consists of REE, and in sample 16 , Na constitutes only a third of the site population, whereas the rest is a mixture of heavier elements. In sample 6, the crystal in which W exceeds Nb in $M(3), \mathrm{Na}$ is almost fully replaced by Sr . The reason for the capability of the $\mathrm{Na}(4)$ site to incorporate such elements as $R E E$ and Sr is found in the local stereochemistry around the $\mathrm{Na}(4)$ site (Fig. 10). Two of the nine ligands to $\mathrm{Na}(4)$ are $O(19)$ ions that are shared with $M(3)$ and $M(2)$, the latter of which becomes five-fold-coordinated because of $O(19)$. In the present selection of crystals, the site-occupancy factor for $O(19)$ varies from about one third to unity (Table 9). It follows from the configuration around $O(19)$ that its presence not only facilitates the accommodation of diand trivalent elements in $N a(4)$, but also ensures the six-fold coordination of $M(3)$ and favors the five-fold coordination of $M(2)$ at the expense of four-fold coordination. As would be expected, there is a strong correlation between the site-occupancy factors of $O(19)$ and the site-scattering values of $N a(4), M(3)$ and $M(2,5)$, respectively.

## The $X$ sites

The two $X$ sites in the $R 3 m$ type of eudialyte ideally have point symmetry $3 m$. However, both sites are strongly disordered along the triad axes and along the mirror planes; a typical situation is seen in Figure 10. The same situation occurs in the $R 3$ and $R \overline{3} m$ type of eudialyte.

The $X$ sites are bonded only to Na. Their site-scattering values are shown in Table 9. When converted to $2(\mathrm{Cl}, \mathrm{F}, \mathrm{OH})$ apfu, any of which may be dominant, there is usually a surplus of electron density that is calculated as $\mathrm{H}_{2} \mathrm{O}$.

## Degree of Acentricity

In Figures 11a, b and c , the $\left|E^{2}-1\right|$ values listed in Table 3 are plotted against various chemical quantities that prove to be determining factors in the degree of acentricity of structures of eudialyte (s.l.). E-statistics are often not very useful in determining acentricity in mineral structures, as many of these statistics are strongly affected by heavy, centrosymmetrically related cations. In the eudialyte structure, a large number of atoms has an approximately uniform atomic number (228 atoms of oxygen, 9 transition metals, 75 atoms of $\mathrm{Si}, 63$ atoms of alkaline-earth elements per unit cell). This uniform mass of scatterers effectively overcomes the problem of non-uniform statistics. The one anomalous value of $I E^{2}-1 \mid$ noted earlier for sample 5 (labeled h in Fig. 11) is a consequence of merohedral twinning. The result of twin overlap of two diffracting lattices is an increase in all $|E|$ values, thus lowering $\left|E^{2}-1\right|$ beyond the theoretical value of 0.736 for acentric structures.

The framework consisting of the silicate rings and [ $\left.\mathrm{ZrO}_{6}\right]$ octahedra is essentially centrosymmetric. The violation of centricity is due to minor adjustments in the rest of the structure. Likewise, the $\left[M(1) \mathrm{O}_{6}\right]$ octahedron is not found to play a major role in this context; the substitutions taking place in $M(1)$ are not well correlated with $\mid E^{2}-1 I$. Only a few parameters related to $M(1)$, such as the bond-length $M(1)-\mathrm{O}(8)$, show a good correlation, possibly because of the interaction with other polyhedra like $N a(4)$ and the tilted $S i(3)$ tetrahedron. The $\left[M(2) \mathrm{O}_{n}\right]$ polyhedra, on the other hand, do show a correlation with acentricity, not by considering individual elements, but by considering the ratio of the sitescattering values of $M(2,4)$ and $M(2,5)$, i.e., the quantity $M(2,5)$ epfu / $[M(2,5)$ epfu $+M(2,4)$ epfu], which clearly is negatively correlated with $\left|E^{2}-1\right|$.

The elemental contents in the $M(3)$ and $\operatorname{Si}(7)$ sites have the primary influence on acentricity. The correlation between these parameters is best illustrated as a $M(3) /[M(3)+S i(7)]$ versus $\left|E^{2}-1\right|$ diagram. The $M(3)$ and $\operatorname{Si}(7)$ elemental quantities are defined in Figure 9.

In simplified terms, the Nb -rich samples of eudialyte are the most strongly acentric, whereas the Si-rich samples of eudialyte are the most strongly centric. As would be expected from this relationship, there is also a strong positive correlation between the site-occupancy factor for $O(19)$ and the degree of acentricity.

It has been shown that $R E E$ and Sr are the main elements substituting for Na , and that the substitution primarily involves $N a(4)$, to a much lesser extent in the

Fig. 11. The correlation between the $\left|E^{2}-1\right|$ values from Table 3 and a) the ratio $M(3) /[M(3)+S i(7)]$ (defined in text), b) the proportion of $R E E$ in apfu, and c) the calculated density. The symbols chosen are as in Table 1.
pseudocentrosymmetrically related $N a(3)$, and only infrequently in other $N a$ sites. Figure 11b shows how this heterogeneous distribution of $R E E$ in $N a$ sites results in a significant impact on the acentricity. The pronounced outlier in the plot trend is the Sr-rich sample 6 (labeled m ), which would have been compliant if Sr had been included in the ordinate component.

With a classic eudialyte rich in $\mathrm{Na}, \mathrm{Ca}, \mathrm{Fe}$ and Si as a starting point, we conclude that all major substitutions, except the $\mathrm{Fe} \Leftrightarrow \mathrm{Mn}$ substitution, proceed from relatively light elements toward relatively heavier elements. Consequently, the correlations hitherto described in Figures 11 a and 11 b can be combined as shown in Figure 11c, where the calculated density is plotted against $\mid E^{2}-1 \mathrm{I}$. The correlation shown is almost perfect ( $r=-0.96$ ), with only two samples slightly off the trend. Sample 9 (labeled V) is actually on a different slope because one sixth of the Zr is substituted by Ti , i.e., it is on a trend toward alluaivite. The deviation of the other sample 7 (labeled w) may be because the microprobe data do not pertain to the crystal used in the structure analysis but is actually from another fragment of the same specimen.

## Solid-Solution Series

The solid-solution series between the classic eudialyte (rich in $\mathrm{Si}, \mathrm{Ca}, \mathrm{Fe}$ and Cl ) and kentbrooksite (rich in $\mathrm{Nb}, R E E, \mathrm{Mn}$ and F) suggested by Johnsen \& Gault (1997) was based on a number of simple correlations between individual elements or small groups of elements. The present crystal-chemical study confirms this series, with minor modifications. A first modification is that the anion parts of the end members may not be significant in the definition of the solid-solution series. Another modification of limited impact is the replacement of Si with ( $\mathrm{Si}, \mathrm{Al}$ ) in the expression for the eudialyte end-member. The most significant modification is the replacement of Nb in the expression for the kentbrooksite end-member with the component defined as the $M(3)$ elements in accordance with Figure 9 and the discussion connected to it. These modifications result in the correlation diagram shown in Figure 12, where it is particularly notable that the series extends beyond kentbrooksite (sample 13, labeled A) and right up to crystal 5 (labeled h), the $R 3$ eudialyte. Also, note that the degree of acentricity is an integral part of the description of the series, with the most centric samples of eudialyte being confined to the right part of the trend and an increasing degree of acentricity to the left. The coefficient of correlation in Figure 12 is $r=-0.97$.

## The Derivation of a Structural Formula

One of the primary objectives of this study was the derivation of a method for the calculation of a structural formula. Until now, there has been no clear means of determining an empirical formula for eudialyte from the
results of a chemical analysis. Ambiguities in number, and types, of atomic sites have led to great confusion and significant errors in the formulae assigned to this mineral. Indeed, this study confirms the complexity of the structure, with almost all sites being able to accommodate more than one cation, and with a notable variation in the total number of anions. Therefore, an accurate formula can only be constructed from data based on structural information. An empirical formula acceptable in most cases may, however, be derived from results of a chemical analysis by use of two different points of reference: 1) total number of anions, or 2) the sum of cations in $\operatorname{Si}(1)$ to $S i(7), M(3)$ and $Z r$ sites.

The total number of anions ( $Z=3$ ) seen in Table 2 ranges from 75.39 to 78.70 apfu, with a mean of $77.38(83)$ apfu for all samples. This gives a standard deviation of $1.07 \%$ of the mean value, which is somewhat higher than desirable. More important, however, is the fact that unless a determination of the proportion of $\mathrm{H}_{2} \mathrm{O}$ is available (usually it is not), the apfu values based on numbers of anions become systematically too high. As an example, in a typical sample of eudialyte, the proportion of Si (apfu) will decrease from 25.90 to 25.30 with the incorporation of $1 \mathrm{wt} . \% \mathrm{H}_{2} \mathrm{O}$. The lack of determinations of other cations will, of course, give a similar effect. Therefore, additional corrections may be required if this method of formula calculation is adopted.

Fig. 12. The solid-solution series between eudialyte (Eud) and kentbrooksite (Ktb), with an extension to the R3 type of eudialyte. The proportions of the Eud and Ktb components are expressed in terms of the amounts of $[(\mathrm{Si}, \mathrm{Al})+$ $\mathrm{Ca}+\mathrm{Fe}]$ and $[(\mathrm{Nb}$, other $M(3)$ elements $)+R E E+\mathrm{Mn}]$, respectively, expressed in apfu. The symbols chosen are as in Table 1.

The second method is based on the number of cations accommodated in the framework composed of the silicate rings and the $Z r$ octahedra, supplemented with the two sites [ $M(3)$ and $\operatorname{Si}(7)]$ in the centers of the ninemembered rings, i.e., $\mathrm{Si}+\mathrm{Al}+\mathrm{Zr}+\mathrm{Ti}+\mathrm{Hf}+\mathrm{Nb}+\mathrm{W}$ + Ta, ideally adding to 29 apfu $(Z=3)$. In all the present samples, these elements add to 29.08(26) apfu with the standard deviation being $0.89 \%$, i.e., slightly better than in the anion-based method of calculation. The real advantage of this second method is the fact that it is fully applicable without determinations of hydrogen or other cations, making the method very practical, as most chemical information is obtained by electron-microprobe analysis. One disadvantage is that some of the elements involved ( $\mathrm{Al}, \mathrm{Ti}$ and Zr ) occasionally also occur in other parts of the structure. For instance in samples 9 and 17, quantities of $\mathrm{Al}, \mathrm{Ti}$ and Zr are found in $M(1)$ and $M(2)$, although only in small amounts. If these two crystals were omitted from the average, the mean would be 29.01(18) apfu, i.e., a standard deviation of $0.62 \%$ only, demonstrating that this method of calculation works well for the majority of eudialytegroup samples. Another minor disadvantage of the method is that it does not account for any site vacancy in $M(3)$, as has been observed in some crystals. Everything considered, though, we conclude that the second method is definitely superior to the first. Thus we recommend the following procedure to arrive at the empirical formula of a eudialyte-group mineral on the basis of chemical data only:
i) For the majority of the eudialyte (s.l.) samples, the empirical formula will be of the type: $\mathrm{Na}_{15}[M(1)]_{6}$ $[M(2)]_{3} \mathrm{Zr}_{3}[M(3)]\left(\mathrm{Si}_{25} \mathrm{O}_{73}\right)\left(\mathrm{O}, \mathrm{OH}, \mathrm{H}_{2} \mathrm{O}\right)_{3} X_{2}$
ii) Calculate the apfu based on 29 (sum of $\mathrm{Si}, \mathrm{Al}$, $\mathrm{Zr}, \mathrm{Ti}, \mathrm{Hf}, \mathrm{Nb}, \mathrm{W}$ and Ta ), and constrain all Fe and Mn to be divalent.
iii) Assign all $\mathrm{Si}+\mathrm{Al}$ to sum to 25 Si apfu. Any excess Si should be added to $M(3)$.
iv) Assign all Zr to the Zr site, and if deficient make up a total to 3 atoms with Ti .
v) Assign all Nb and W to $M(3)$.
vi) Assign all Fe and Mn to $M(2)$. Any excess Mn should be assigned to $M(1)$.
vii) Assign all Ca to $M(1)$ and any remaining Mn then Y and REE to bring the total to 6 atoms. Any excess Ca should be assigned to the $N a$ sites.
viii) Assign all $\mathrm{Na}, \mathrm{K}, \mathrm{Sr}$ and remaining Ca and $R E E$ to the $N a$ sites.
ix) Assign 73 of the O atoms to the silicate rings, with the remaining anions partitioned into an O fraction and a halogen fraction.
x) The number of H atoms is based on charge balance.

Within the eudialyte group, the species eudialyte [i.e., the type material of the original description of Stromeyer (1819)] would have the formula $\mathrm{Na}_{15} \mathrm{Ca}_{6}$ $\mathrm{Fe}_{3} \mathrm{Zr}_{3} \mathrm{Si}\left(\mathrm{Si}_{25} \mathrm{O}_{73}\right)\left(\mathrm{O}, \mathrm{OH}, \mathrm{H}_{2} \mathrm{O}\right)_{3}(\mathrm{Cl}, \mathrm{OH})_{2}$, and kentbrooksite (Johnsen et al. 1998), the formula

## $\mathrm{Na}_{15} \mathrm{Ca}_{6} \mathrm{Mn}_{3} \mathrm{Zr}_{3} \mathrm{Nb}\left(\mathrm{Si}_{25} \mathrm{O}_{73}\right)\left(\mathrm{O}, \mathrm{OH}, \mathrm{H}_{2} \mathrm{O}\right)_{3}(\mathrm{~F}, \mathrm{Cl})_{2}$.

In order to encompass all samples studied, the empirical formula must be expanded to: $\mathrm{Na}_{12}[\mathrm{Na}(4)]_{3}$ $[M(1 \mathrm{a})]_{3}[M(1 \mathrm{~b})]_{3}[M(2)]_{3} \mathrm{Zr}_{3}[M(3)]\left(\mathrm{Si}_{25} \mathrm{O}_{73}\right)(\mathrm{O}, \mathrm{OH}$, $\left.\mathrm{H}_{2} \mathrm{O}\right)_{3} X_{2}$. Rare cases where Ca apfu is below $50 \%$ of the $M(1)$ site or Na is below $50 \%$ in the $N a(4)$ site will become evident during the course of formula calculation. However, in such cases, we believe that a crystalstructure refinement is required in order to calculate a reliable formula.

## Conclusions

Minerals of the eudialyte group have a complex structure with a wide variation in chemical substitutions. A complete formula requires crystal-structure data. An acceptable empirical formula, based on chemical analysis only, can be calculated from the relationships derived in this study, however. Relationships determined in this study that are of particular importance are summarized here:

1) A fundamental property of the eudialyte structure is a stable network of three-membered and ninemembered rings of $\left[\mathrm{SiO}_{4}\right]$ tetrahedra. No chemical substitution is noted in these tetrahedra. Only small adjustments involving tilting or rotation of the $\left[\mathrm{SiO}_{4}\right]$ tetrahedra are required to accommodate other modules.
2) The $\left[M(1) \mathrm{O}_{6}\right]$ octahedron is more or less distorted. It is usually dominated by Ca , but variable amounts of Mn, REE and Y can be present. Both bond lengths and the degree of distortion of the octahedron are well correlated with chemistry. In one crystal, more than half the Ca is replaced by Mn and $R E E$, resulting in an ordering of these cations in a Mn-dominated $M$ (1a) site and a Ca- and REE-dominated $M(1 \mathrm{~b})$ site.
3) The $M(2)$ site has either four-fold coordination with an almost planar arrangement or five-fold coordination with a distorted square pyramid, $O(19)$ being the fifth ligand. Iron definitely prefers the $M(2,4)$ site, whereas Mn generally dominates in $M(2,5)$. The occupancy of the two sites combined seldom reaches the maximum 3 apfu, but is invariably higher than $\sim 2$ apfu, indicating that the $M(2)$ site is an integral part of the structure.
4) The $M(3)$ and $\operatorname{Si}(7)$ sites, the two central sites of the two crystallographically distinct nine-membered silicate rings, are related by the substitution ${ }^{[6]} M(3)+$ ${ }^{[4]} \mathrm{Si}(7) \leftrightarrow 2{ }^{[4]} \mathrm{Si}(7)$. The $\left[M(3) \mathrm{O}_{6}\right]$ octahedron incorporating $O(19)$ is predominantly occupied by Nb (seldom W ), whereas the $\left[\mathrm{Si}(7) \mathrm{O}_{4}\right]$ tetrahedron pointing upward or downward accommodates ( $\mathrm{Si}, \mathrm{Al}$ ).
5) Na occupies sites varying in coordination number from 6 to 10 . The $\mathrm{Na}(4)$ site, with nine-fold coordination, is particularly suitable for incorporation of elements such as $R E E, \mathrm{Sr}, \mathrm{Ca}$ and K .
6) $O(19)$ plays a key role in the eudialyte structure, being the ligand shared by the $M(3), M(2,5)$ and $N a(4)$
sites. The site-occupancy factor of $O(19)$ and the epfu values of these cations sites are strongly correlated.
7) Eudialyte sensu lato crystallizes in space groups $R \overline{3} m, R 3 m$ or $R 3$, depending on the degree of disorder and the chemical content of certain sites. Eudialyte sensu stricto is ideally centrosymmetric, and as substitutions of the type $\mathrm{Si} \rightarrow(\mathrm{Nb}, \mathrm{W}), \mathrm{Fe} \rightarrow \mathrm{Mn},(\mathrm{Ca}, \mathrm{Na}) \rightarrow$ ( $R E E, S r$ ) take place, the structure becomes progressively more noncentrosymmetric.
8) $\left|E^{2}-1\right|$ values prove useful in displaying the degree of acentricity in the eudialyte structure, as this parameter shows strong negative correlations with the chemical quantities such as $M(3) /[(M(3)+S i(7)]$ and the proportion of REE in apfu. Since the substituting elements are in general heavier than those replaced, an almost perfect negative correlation exists between $\mid E^{2}$ $-1 \mid$ and the calculated density.
9) The solid-solution series between the classic eudialyte and kentbrooksite is confirmed with minor modifications. The series extends beyond kentbrooksite to the $R 3$ eudialyte. The degree of acentricity is an integral property of the series.
10) From results of a chemical analysis, the number of atoms in the formula may be calculated on the basis of the cation sum ( $\mathrm{Si}+\mathrm{Al}+\mathrm{Zr}+\mathrm{Ti}+\mathrm{Hf}+\mathrm{Nb}+\mathrm{W}+$ $\mathrm{Ta})=29$. As the number of anions varies, an approach based on anions is not a suitable basis for the calculation of a formula.
11) The generalized empirical formula is $\mathrm{Na}_{15}$ $[M(1)]_{6}[M(2)]_{3} \mathrm{Zr}_{3}[M(3)]\left(\mathrm{Si}_{25} \mathrm{O}_{73}\right)\left(\mathrm{O}, \mathrm{OH}, \mathrm{H}_{2} \mathrm{O}\right)_{3} X_{2}$. Elements may be reliably assigned to each site with a series of prescribed steps.
12) To date, only two species have been formally described within the eudialyte group, but several more are imminent. The described species are eudialyte, $\mathrm{Na}_{15} \mathrm{Ca}_{6} \mathrm{Fe}_{3} \mathrm{Zr}_{3} \mathrm{Si}\left(\mathrm{Si}_{25} \mathrm{O}_{73}\right)\left(\mathrm{O}, \mathrm{OH}, \mathrm{H}_{2} \mathrm{O}\right)_{3}(\mathrm{Cl}, \mathrm{OH})_{2}$, and kentbrooksite, $\mathrm{Na}_{15} \mathrm{Ca}_{6} \mathrm{Mn}_{3} \mathrm{Zr}_{3} \mathrm{Nb}\left(\mathrm{Si}_{25} \mathrm{O}_{73}\right)(\mathrm{O}, \mathrm{OH}$, $\left.\mathrm{H}_{2} \mathrm{O}\right)_{3} \mathrm{~F}_{2}$.

Even after this extensive study, eudialyte remains an enigmatic mineral, as a number of problems still exist. Several eudialyte crystals originally included in this study did not refine well, although the crystals look good physically, and the intensity data give sharp reflections, with good cell refinements. In spite of the experience we have gained with the eudialyte structure (i.e., trying various models with differing space-groups, twin laws and order-disorder arrangements), we have no explanation for the poor refinements, which generally do not attain $R$ indices below 0.07 . Of particular interest for future investigation will be eudialyte crystals with extraordinary compositions, for example with exceptional enrichments in Zr, REE or Nb , or depletions in Na . These further studies are primarily of crystal-chemical interest, whereas the present paper establishes the chemical formula and major chemical substitutions within this group of minerals for those species of economic and petrological importance.

## Acknowledgements

We are indebted to R.A. Gault, Canadian Museum of Nature, for his continued and stimulating interest in minerals of the eudialyte group and for his very careful electron-microprobe analyses of the crystals used in this study. We thank F.C. Hawthorne, University of Manitoba, for the use of the single-crystal diffractometer, and M.A. Cooper, also at that institution, for some of the data collections. R.W. Berg, the Technical University of Denmark, and E.A. Moffat, Canadian Conservation Institute, are thanked for providing the infrared spectra, and J.-E. Jørgensen, the University of Århus, for supplying the thermogravimetric analyses. U. Hålenius, the Swedish Museum of Natural History, is thanked for sharing his Mössbauer and optical absorption spectroscopy data with us. The manuscript was improved by the comments and suggestions of the referees A.R. Chakhmouradian and J. Swope, and of Associate Editor R.H. Mitchell and Editor R.F. Martin. The work at the University of Copenhagen was supported by the Danish Natural Science Research Council.

## Note Added in Proof

Sample numbers 6 and 5 in the present study have subsequently gained status as new mineral species. They are named khomyakovite (Johnsen et al. 1999a) and oneillite (Johnsen et al. 1999b), respectively. The new mineral species and their names have been approved by the Commission on New Minerals and Mineral Names, IMA.
