ABSTRACT. — Isotope geochronology has contributed a great deal to reconstruction of the geological evolution of Central Alps, since it has enabled the difficulties arising from the absence of geological evidence for most of the pre-Carboniferous events to be overcome.

Three main petrogenetic periods can be identified:

1) Between 480 and 420 m.y. a metamorphic event (whose importance can be only guessed at), followed by discrete intrusive activity, formed the stratigraphical framework of all Units of the Central Alpine basement, although its ensialic character points to the presence of an unknown (or unidentifiable) substratum.

2) Between 350 and 270 m.y.: the important Hercynian diastrophism and metamorphism followed by an intense, mostly acidic magmatic activity that probably remobilised the substratum. This event is actually the most important, for both the South-alpine and the Austroalpine basement, but it is also responsible for most of the features of the Pennidic domain.

3) From 90 m.y. (Eoalpine phase) till today, though with a metamorphic climax at 38 m.y., a differentiated cooling history and a complex post-orogenic intrusive activity: this is the Alpine Orogeny. Detailed isotopic surveys have allowed a mantle origin with different degrees of crustal contamination to be attributed to most of the Alpine magma.

Key words: Central Alps, Geochronology, Southern Alps, Austroalpine Domain, Pennidic Domain.

Riassunto. — La geocronologia isotopica ha fornito un contributo considerevole alla ricostruzione dell'evoluzione geologica delle Alpi Centrali. Sono stati distinti tre periodi petrogenetici principali:

1) Tra 480 e 420 m.a.: un evento metamorfico (sulla cui importanza si possono fare solo congetture), seguito da una discreta attività magmatica,

formò l'impalcatura stratigrafica di tutte le unità del basamento delle Alpi Centrali, sebbene il carattere ensialico dell'evento testimoni l'esistenza di un substrato sconosciuto o non identificabile.

2) Tra 350 e 270 m.a.: l'importante diastrofismo e metamorfismo Ercinico, seguito da una intensa attività magmatica, che probabilmente fu il risultato di una generale rimobilizzazione del substrato. L'evento Ercinico fu, in effetti, il più importante per il basamento Sudalpino e Austroalpino, ma fu anche responsabile della creazione di molti dei caratteri litologici del dominio Pennidico.

3) Da 90 m.a. (fase Eoalpina) fino ad oggi, ma con un culmine metamorfico a 38 m.a., una storia differenziata di raffreddamento ed una complessa attività intrusiva postorogenica: questa è l'orogenesi Alpina. Ricerche isotopiche di dettaglio hanno permesso di attribuire alla maggior parte dei magmi alpini un'origine dal mantello, con diversi gradi di contaminazione crostale.

Parole chiave: Alpi Centrali, Geocronologia, Sudalpino, Austroalpino, Pennidico.

Introduction

The central sector of the Alps is probably the part of the Earth's crust that has been studied in the greatest detail and for the longest time, since modern geology was born here in the nineteenth century. Its radiometric data are also very abundant, mostly thanks to the presence of the important schools of Berne, Zürich and Pisa.

Surprisingly enough, many geochronological problems are still open and many controversies still survive, demonstrating that the deeper the studies and the harder the problems of interpretation become.

For the sake of clarity we will divide our discussion into three parts:

- 1 - Prealpine history of the Southalpine and Austroalpine basement.
- 2 - Prealpine and Alpine history of the Pennidic domain.
- 3 - Post-collisional Alpine magmatism.

1. Prealpine history of the Southalpine and Austroalpine basements

1.1. SOUTHALPINE BASEMENT

Once the Archaic age of the « crystalline rocks » postulated by the neptunists was put aside, it became clear that the metamorphic rocks composing most of the Southalpine basement have undergone at least one pre-Alpine orogeny. Their dominating meta-sedimentary nature was immediately understood, whilst the igneous origin of the interlayered « granitic » gneisses was not fully recognized, since « transformism », the dominating theory of the first half of our century, induced many investigators to see in them only the product of extensive metasomatism.

NOVARESE (1929) recognized the pre-Carboniferous age of metamorphism and proposed a Silurian age for sedimentation, on the basis of lithological analogy with other non-metamorphic shales.

The granites cutting the metamorphic rocks were identified as pre-Alpine (except by STAUB, 1949).

The only geochronological evidence was, at that time, the « Hercynian unconformity », i.e. the folded and eroded metamorphic rocks were overlain by a pre-Triassic continental conglomerate that VENZO & MAGLIA (1947) identified as Carboniferous (Westphalian B) on the basis of its fossiliferous content.

Rb-Sr and K-Ar mineral ages

The first geochronological data on metamorphic rocks appeared in 1966 (HANSON et al.), when a K-Ar age was assigned to a biotite from a schist, and several Rb-Sr ages on white mica from the pegmatite on the eastern shore of Lake Como. The ages (table 1) range from 200 to 250 m.y.; since they appeared too young to be attributed

to the Hercynian metamorphism, the authors proposed that the formation underwent a radiogenic loss during a thermal event connected with the Permian magmatic activity. This Permian thermal event is evoked from time to time as a « deus ex machina » to explain radiogenic loss, even though it has not yet gained geological or petrographic support. The possibility that radiogenic loss was due to Alpine rejuvenation was considered less likely.

Rb-Sr and K-Ar mineral ages on para- and ortho-metamorphic rocks of the central Southalpine basement, offered by Mc DOWELL & SCHMID (1968), Mc DOWELL (1970), HUNZIKER (1974), BOCCIO et al. (1981), BORIANI et al. (1982-83), MOTTANA et al. (1985) (tables 1 and 2), have confirmed the Hercynian age of the last detectable metamorphic event; moreover it has become evident that there is a constant decrease in mineral ages from SE to NW.

The most obvious meaning of this pattern, if we interpret mineral ages as cooling ages, is that it reflects the post-Hercynian cooling history of the Southern Alps; this is geologically substantiated by the evidence that the degree of metamorphism also increases from SE to NW. Moreover, the increasing Rb-Sr white mica age towards E (up to 364 ± 15 m.y. in Val Trompia: DEL MORO in RIKLIN, 1983) may reflect an older age in the more easterly part (i.e.: the metamorphic « thermal wave » propagated from SE to NW). Yet one must remember that, depending on the crustal level, the lower the metamorphic grade, the faster the cooling down during the uplift of the Hercynian belt. Nevertheless, other explanations have been considered, such as the possibly more conspicuous radiogenic loss near the Insubric Line during the Alpine orogeny; in this case, we would be dealing with mixed ages and not with cooling ages.

The particular K-Ar mica and whole rock pattern found by BOCCIO et al., 1981, was initially ascribed to the presence of two distinct events: a Caledonian and a Hercynian metamorphism. This interpretation has never been shared by other workers and is no longer held by the authors themselves (MOTTANA et al., 1985), who now attribute the younger ages to a late-Triassic metamorphic event.

U-Pb mineral ages

U-Pb zircon and monazite ages both on para- and ortho-gneisses have made a very important contribution to reconstruction of the geological history. They have also been a source of confusion, since the «transformist» interpretation of the granitic gneisses as granitized rocks («*Orthogneis Typus*», REINHARD, 1964), led authors to confuse intrusion ages with metamorphic ages.

If we separate para- from ortho-metamorphic rocks we find the following distribution:

1 - U-Pb zircon ages of paragneisses are all discordant, with an upper intercept between 1900 and 2500 m.y., and a lower intercept between 400 and 500 m.y. (except in the Ivrea-Verbano Zone, about 300 m.y.).

2 - U-Pb zircon ages of orthogneisses are all concordant or nearly so around a value of 420-465 m.y.

3 - U-Pb monazite ages of paragneisses are concordant in the Ivrea-Verbano Zone around a value of 275 m.y.; a granitic gneiss, with post-kinematic mobilization near the contact between Strona-Ceneri and Ivrea-Verbano in Valle Strona di Omegna, also contains a monazite with concordant age of 275 m.y. (KÖPPEL, 1974).

4 - A U-Pb concordant monazite age of 450 m.y. was obtained by KÖPPEL & GRÜNNENFELDER (1971) on a paragneiss (*Cenerigneiss*) of the Strona Ceneri Zone occurring at Ponte Casletto (Valle S. Bernardino).

Particular problems have been encountered in the U-Pb zircon dating of the «*Gneiss Chiari*» of the Val Colla Zone, a leucocratic coarse grained gneiss that seems to form the uppermost horizon of the metamorphic basement of the Southern Alps. The «*Gneiss Chiari*» have been interpreted as metaarkose (EL TAHAWI, 1965), migmatites (LIBORIO & MOTTANA, 1971; KÖPPEL & GRÜNNENFELDER, 1971), and metarhyolites (BORIANI & COLOMBO, 1979); their zircons give highly discordant ages (KÖPPEL & GRÜNNENFELDER, 1971), ranging from 140 to 580 m.y.. The problem of their age is still open.

All these data were seen as evidence of two metamorphisms («Caledonian» and Hercynian, the former being cancelled in

the high-grade Ivrea-Verbano Zone). In view of the initial error concerning the origin of orthogneisses, however, there is very little evidence of a significant «Caledonian» metamorphism. Concordant zircon ages clearly date the intrusion of the Ordovician plutonic rocks, whilst the interpretation of the lower intercept of discordant zircons is far from being universally accepted. Only the concordant monazite age of 450 m.y. of the *Cenerigneiss* of Ponte Casletto seems to indicate a real metamorphic event at that time: why not a contact metamorphism induced by an Ordovician intrusion? The *Cenerigneiss* of Ponte Casletto is bordered by an orthogneiss.

In view of the purpose of this paper, mention must also be made of the very different interpretation proposed by ALLEGRE et al. (1974) for the discordant zircon ages: using a multiepisodic model of lead loss, they dated the source rocks of the original sediments at about 2500 m.y., with losses at 520-580 m.y. (Cadomian), 300 m.y. (Hercynian) and 30 m.y. (Alpine).

Rb-Sr w.r. isochrons

Only two good isochrons are available for the zone under consideration and both are on its westernmost part. One isochron (HUNZIKER & ZINGG, 1980) — on the paragneisses of the Ivrea-Verbano Zone — indicates isotopic homogenization at 478 ± 20 m.y. (*i.r.* = 0.7086). Since generalized degranitization through partial melting is assumed, it is regarded as dating the climax of metamorphism and not the first weak metamorphic episode. The conclusion is thus drawn that the Ivrea-Verbano zone underwent a strong «Caledonian» metamorphism and then cooled down slowly through the Upper Paleozoic without a real Hercynian disturbance.

The other isochron was obtained by BORIANI et al. (1982-83) on the «Serie dei Laghi» orthogneisses, and gave an age of 466 ± 5 m.y. (*i.r.* = 0.7087). The most obvious interpretation is that this age records the intrusion of the tonalites, granodiorites and granites from which the orthogneisses derived; ZINGG (1983) suggests it may represent the age of the metamorphism of the orthogneisses, even though many isochrons (see for example: BORSI et al., 1973-

1980) clearly demonstrate Ordovician magmatism in the analogous Austroalpine domain.

Reference must also be made to the isochron obtained by HAMET & ALBARÈDE (1973), from five samples of Strona-Ceneri paragneisses: 555 m.y. (543 with $\lambda = 1.42$) and an $i.r. = 0.713$ (errors not quoted), indicative of a significant Cadomian event. The meaning of this isochron is discussed by HUNZIKER & ZINGG (1980) who suggest that the size of the samples may have been a source of error.

DEL MORO (pers. com.) obtained a preliminary reference isochron of 459 ± 66 m.y. on the « Scisti di Edolo ».

As can be seen, the Rb-Sr isochrons on paragneisses point to a « Caledonian » metamorphic event. The intensity of that event, however, is still matter of speculation. In our opinion, there is much geological and petrographical evidence of a significant Hercynian diastrophism and metamorphism; the « Caledonian » w.r. isochrons may reflect a weak, petrographically undetectable, regional metamorphism, or even a thermal event connected with the Ordovician magmatism.

A very interesting attempt to estimate the maximum age of deposition of the sediments from which the Ivrea-Verbano paragneisses derived has been made by HUNZIKER & ZINGG (1980). Extrapolation of the Sr isotopic ratio on a combined Compston/Jeffery/Nicolaysen diagram, gave a maximum age of 700 m.y.. The upper intercept of the discordant zircons indicated 1900-2500 m.y. for the very old continental crust that was the source of the sediments deposited over an unknown continental substratum in the Late-Precambrian or in the Cambro-Ordovician.

The source area cannot be identified. It must have been in either the North European or the African shield.

Turning to the Ordovician magma, BORIANI et al. (1982-83) maintain that the initial Sr ratio of 0.7087 reflects its crustal origin, though hornblende-bearing orthogneisses, plotting below the isochron, point to a deeper origin. HUNZIKER & ZINGG (1980) had proposed a connection between « degranitization » of the granulite facies Ivrea-Verbano zone and the origin of these orthogneisses.

ZINGG (1983) now admits that this is not possible in the light of KÖPPEL & SCHROLL's (1983) new data on the isotopic composition of Pb in the two formations.

1.2. SYN-, POST-METAMORPHIC MAGMATIC ROCKS OF THE SOUTHALPINE

The Southalpine basement contains small and large bodies of intrusive rocks and is overlain by Permian rhyolitic volcanites.

The oldest intrusive body seems to be that of the Ivrea Zone; it consists of a layered basic complex intruded into high-grade paragneisses and marbles, and of minor mafic bodies (of debated origin) interlayered in the same country rocks; the igneous rocks show textures and parageneses fully or partly re-equilibrated at granulite facies conditions.

Intrusion of the Ivrea body is seen by HUNZIKER & ZINGG (1980) as the cause of high-grade metamorphism, whereas GARUTI et al. (1980) suggest that it occurred after the regional metamorphic peak. Unfortunately, no direct isotopic age measurements are available for the mafic rocks.

GRAESER & HUNZIKER (1968) obtained an isochron of about 310 m.y. (338 ± 41 m.y., $i.r. = 0.7128$, recalculated by HUNZIKER & ZINGG, 1980, for $\lambda = 1.42$) on paragneiss bands near the contact with the Anzola gabbro (Val d'Ossola) and concluded that the maximum age for the gabbro intrusion was 300 m.y.. HUNZIKER & ZINGG (1980) argue that all these bands, when taken together as one big sample, plot on the 478 m.y. isochron of the paragneisses. This corresponds to a change of mind: the 338 m.y. isochron is geologically meaningless and solely determined by the size of the sample.

The intrusion becomes « Caledonian » and its emplacement supplied the heat for the high-grade metamorphism.

The presence of mantle-derived ultramafics in close relationship with the mafic bodies (LENSCH, 1971; RIVALENTI et al., 1975; GARUTI et al., 1980), may represent a crust-mantle transition or emplacement of mantle slabs in the lower continental crust. The petrological data indicate that, if emplaced, they were subsequently re-equilibrated at the granulite facies conditions.

The K-Ar phlogopite age of the phlogopite-peridotite of Finero is 246 m.y. according

to KRUMMENACHER et al. (1960) and 206 ± 9 m.y. according to HUNZIKER (1974). Hornblende (same source), gives a meaningless age of 1290 m.y., due to excess argon (HUNZIKER, 1974).

A Rb-Sr w.r. isochron (HUNZIKER & ZINGG, 1982) on the same rock gives an age of 305 ± 10 m.y. with an *i.r.* = 0.7062 ± 0.0005 : this phlogopite-peridotite represents a contaminated mantle (see also COLTORTI & SIENA, 1984). By linear extrapolation of Sr isotopic ratio values to those of common mantle peridotite of the Ivrea zone on a combined Compston/Jeffery/Nicolaysen diagram (HUNZIKER & ZINGG, op. cit.), put the age of contamination at 350 ± 20 m.y..

In their view, emplacement occurred in « Caledonian » times and crustal contamination in Variscan times owing to the tectonic activity that uplifted the Ivrea-Verbano Zone (see also ZINGG, 1983).

Geochronological study of the other, mostly granitic, igneous rocks of the Southern Alps has not raised any particular problems, though their detailed dating is far from being complete. The first real age determinations were performed by JÄGER & FAUL (1959) on the granites of Baveno and Montorfano, who obtained a Rb-Sr age of about 290 m.y. on biotite and K-feldspar and a K-Ar age of about 260 m.y. on biotite. They attributed the discordance to Ar loss due to weak metamorphism after their emplacement.

The late-Hercynian age of these granites was later confirmed by the U-Pb age measurements on zircons performed by PASTEELS (1964) and by KÖPPEL (1974).

In 1980, HUNZIKER & ZINGG published a Rb-Sr w.r. isochron giving an age of 276 ± 5 m.y. with an *i.r.* = 0.7087 ± 0.0009 . Another isochron published by HUNZIKER (1974) on the Permian volcanites giving an age of 269 ± 13 m.y. with an *i.r.* = 0.710 was recalculated by HUNZIKER & ZINGG (1980) for $\lambda = 1.42$ in 280 ± 5 and an *i.r.* = 0.7071 ± 0.0013 . Plutonites plus volcanites define an isochron of 278 ± 3 m.y. with an *i.r.* = 0.7082 ± 0.0007 .

The six samples from which the granite isochron was obtained are from Camponi (Val d'Ossola) granodiorite, Roccapietra (Valsesia) granodiorite, the pink, alkali-granite of Baveno (two samples), the white

calcalkaline granite of Montorfano and a similar rock from Alzo (Lake Orta). Recent studies (BORIANI et al., in preparation) show that the Camponi granodiorite belongs to the earlier cycle of the late-to-post-Hercynian magmatism, a stage that we can define as late-orogenic and pre-uplift: calcalkaline basic-to-intermediate magma was intruded at the border between the Ivrea-Verbano and Strona-Ceneri Zones, inducing anatexic melting of Strona-Ceneri gneisses (evidence of the deep-seated environment of the intrusion; see also BORIANI et al., 1977).

The Mottarone-Baveno, Montorfano and Alzo-Roccapietra granites belong to the second, post-uplift cycle and were emplaced as a batholith formed by many plutons intruded by a multiepisode cauldron subsidence mechanism. A detailed survey, including geochronological and isotope geology studies, is now under way or planned to distinguish intrusions of different ages and sources.

1.3. AUSTROALPINE BASEMENT (E OF BEL-LINZONA)

The chronological picture of the Austroalpine basement is much less clear. The reason is very simple: age determinations have been mainly concentrated on Alpine and pre-Alpine formations. The Austroalpine rocks bear a fundamental pre-Alpine imprint, but were more or less weakly overprinted by the Alpine metamorphism and this caused a loss of radiogenic isotopes. In other respect, their main metamorphic and igneous events, and the lithological characters are very similar to those of the Southalpine basement. This similarity was not always clear and the age attributions of the recent geological maps of Valtellina need substantial correction in the light of the new evidence.

Rb-Sr and K-Ar mineral ages

The only published mineral ages for the metamorphic rocks are those of HANSON et al. (1966) for a pegmatite of Valle Grosina (Sondrio): the muscovite gives a Rb-Sr age of 252 m.y. and a K-Ar age of 217 ± 11 m.y.. This pegmatite had previously been considered Alpine by KÖNIG (1964). At that time, the age of pegmatite dykes was regarded as independent of metamorphism.

The Valle Grosina pegmatites, as well as all the « pegmatite fields » connected with the transition between medium- and high-grade metamorphism, are now seen as the product of partial melting of muscovite + plagioclase + quartz under hydrous conditions (BORIANI, 1982-83). The muscovite age thus reflects the cooling history after the metamorphic peak, if the region did not suffer a later metamorphic event.

U-Pb mineral ages

Only one measurement has so far been published (even if we are aware that many exist in the drawers of some prudent geochronologists): a U-Pb zircon determination (GRAUERT et al., 1973) on a paragneiss from the contact aureole of the Sondalo basic pluton of Northern Valtellina. The ages are discordant: the upper intercept is about 2050 m.y. and the lower intercept about 400 m.y.. They are similar to those obtained by the same authors on the Austroalpine quartzites of Val Martello and Landeck, as well as those for the Silvretta Nappe and the Southalpine basement.

1.4. MAGMATIC ROCKS OF THE AUSTRO-ALPINE

In contrast with the almost constant late-Hercynian age of the plutonic rocks of the Southern Alps (the exceptions are the Adamello pluton and the small stock of Mialgiano-Biella), the Austroalpine intrusives belong to either the pre-Alpine or the Alpine magmatic cycles. Each magmatic body must be studied in detail geochronologically and geologically. The best evidence is given by the sequence of the metamorphic events: if the Alpine regional metamorphism overprints both the intrusive and the country rocks, the intrusion is pre-Alpine; if the contact metamorphism overprints the Alpine regional metamorphism, the intrusion is late- or post-Alpine.

The Rb-Sr muscovite age of the small granite bodies of the Upper and Medium Austroalpine Nappes of Valtellina (showing greenschist-facies Alpine overprint) is between 259 and 282 m.y., while biotite gives very variable younger ages (224-78 m.y.) (DEL MORO et al., 1982-83; BORIANI

et al., 1982-83). This pattern clearly reflects the lower blocking temperature of the biotite Rb-Sr system, which may have been re-opened by the Alpine metamorphism, resulting in a variable loss of radiogenic Sr, mostly in this mineral.

Only one Rb-Sr biotite age measurement has been performed on the Sondalo basic pluton (242 ± 4 m.y., pers. com. from DEL MORO, NOTARPIETRO and POTENZA).

Pb- α zircon ages of 295-260 m.y. were obtained by BUCHS et al. (1962) on the Bernina intrusive rocks. A U-Pb zircon age of 305 ± 10 m.y., performed by Grünenfelder on a Bernina granite, is cited by RAGETH (1984).

A reference isochron of about 285 m.y. has been published by BORIANI et al. (1982-83) for the Brusio granite.

The radiometric ages of the Austroalpine basement of Central Alps (E of Bellinzona) are enough to show that the pre-Alpine evolution is the same as that of the Southalpine basement. The presence of Permian volcanic rocks in the Bernina group and the few age determinations also suggest that the post-Hercynian igneous activity was similar, though the age and the genetic relationships between the basic and acidic igneous rocks are not yet fully understood.

The Alpine metamorphism induced a grade-dependent loss of radiogenic isotopes; since it was retrogressive, the loss is strictly related to the fluid circulation and hence the degree of Eo-Alpine tectonization.

2. Prealpine and Alpine history of the Pennidic domain

In the Western Alps the Ossola Valley l.s. is one of the most studied geological sections since the past century, because of the complete exposure of Pennidic Units.

All the lower and upper nappes are over-thrust on the deepest, probably autochthonous, element, i.e. the Verampio «granite» in the Antigorio Valley. In Tessin there is another corresponding axial culmination. Here the deepest Unit is the Leventina gneiss. Between these two culminations, there is a synform structure running NS with the Maggia Querzone in the core and hence no continuity between the two areas.

In the Ossola-Antigorio Valley, the ascending lower Pennidic Units are: Antigorio, Lebendun and Monte Leone nappes. The Antigorio nappe is separated from the Verampio « granite » by the « Scisti di Bacceno », a complex of metapelitic rocks with minor marble intercalations.

It mostly consists of granitic orthogneisses with different degrees of deformation, minor paragneisses and rare mesozoic sedimentary sequences occurring as small « klippen » (e.g. Monte Forno, Antigorio Valley).

The Monte Leone nappe, too, mostly consists of granitic orthogneisses with a very typical banded texture recalling the texture of primary thysolithic volcanites.

The Lebendun Unit needs special attention. It is probably not a classic nappe because it appears to have no root zone. It may be a flake of Permo-Carboniferous and Mesozoic cover from the north (ultrahelvetic?) and wedged between the Antigorio and Monte Leone nappes. Its lithological association is strictly analogous to that of the « Bedretto synform » separating the Pennidic Units from the parautochthonous Aar-Gotthard Massif. The series includes a very characteristic horizon on the bottom of Jurassic « Bündnerschiefer » (represented by « Quartenschiefer » or « Garbenschiefer ») and begins with conglomeratic rocks containing pebbles of granitic orthogneisses. These have been given Rb-Sr and K-Ar dates.

The upper Pennidic Units consist of the Monte Rosa nappe and the Moncucco-Orselina-Isorno Series. To the east of Ossola Valley only the vertical southern zone of the Monte Rosa nappe occurs. Known as Monte Rosa Zone, it is separated from the Moncucco Series l.s. by a thin horizon of serpentinites and metabasites (Antrona synform granitic orthogneisses (quartz, megacrysts of « root zone » auct.) and mostly consists of K-feldspar, plagioclase, muscovite/phengite, biotite) and rare paragneisses; these may be the primary basement intruded by granites. The orthogneisses show flaser texture along the border of the mass and augen texture internally.

The Moncucco-Orselina-Isorno Series is an « anomalous » element when compared with the other Pennidic Units. It mostly consists of banded paragneisses l.s. and amphibolitic

paragneisses, with minor orthogneisses, amphibolites and rare serpentinites. The orthogneisses occur in continuous, but rather thin horizons. The Moncucco Series l.s. can be related to the S. Bernardo nappe because of its lithological composition. To the west of the Ossola Valley, at the southern border of the Moncucco Series, there is a thick mass of augengneisses with megacrysts of K-feldspar (Camughera gneisses). This was once regarded as connected to the Moncucco Series; but it shows clear microtextural and structural analogies with the gneisses of the Monte Rosa nappe. The preliminary radiometric data also substantiate the strong analogy between the Camughera and Monte Rosa gneisses and raise the same evolutionary problems. The Camughera gneiss is separated from the Moncucco Series l.s. by a thin and discontinuous horizon of metarhyolites, quartzites and marbles, which may be Permian (primary sedimentary cover?).

In the core of a synform structure in this Series there is a very problematic Unit: the so-called Pioda di Crana Zone. This tectonic element consists of a large, rather homogeneous « slab » of granitic banded gneisses, formerly correlated with the Antigorio nappe. Because of its strongly banded texture and its mineralogical composition it may be of volcanic or volcano-sedimentary origin. Moreover it can probably be correlated with the Monte Leone rather than the Antigorio nappe.

In Tessin, the Simano nappe overlies the Leventina gneisses at the same structural level as the Antigorio nappe. It mostly consists of orthogneisses. The uppermost nappe, the Maggia nappe, seems to be analogous to the Moncucco Series l.s. lithologically, but is not directly connected with it.

In Alpine age, all the Simplon-Tessin area underwent a metamorphic event of medium to high grade from west to east, which almost completely obliterated the older metamorphic features. The tectonic Units are all within the staurolite isograds; to the east, there is a transition from staurolite to kyanite and to sillimanite. Sillimanite appears in the eastern Vigezzo Valley and coincides with the occurrence of unmetamorphosed pegmatites. These are more frequent in Tessin near Locarno and Bellin-

zona, which is right in the thermal core of the Lepondine dome.

In the Pennidic Units of the Western Alps the radiometric datings are mostly for orthogneisses. Few pegmatites and paragneisses have been studied. There are also Rb-Sr whole rock isochrons. The methods most used are Rb-Sr and K-Ar on biotite and muscovite/phengite. There are few U-Pb data on zircons and monazites and very few on the apatite fission track.

The geological setting described is based on several notes and maps, mainly STEINER (1984 a), BIGIOGGERO et al. (1980), TRÜMPY (1980 a, b), CARTA TETTONICA DELLA SVIZZERA (1980), CARTA GEOLOGICA DELLA SVIZZERA (1980), KLEIN (1978), BOCQUET et al. (1973-74).

2.1. LOWER PENNIDIC UNITS

Rb-Sr and K-Ar ages

There are only ages on biotite and muscovite/phengite from Verampio, Antigorio and Monte Leone orthogneisses; in the Lebendun Series there are ages on micas from psammitic gneisses and their embedded orthogneiss pebbles.

The data are not problematic: in the Ossola area Rb-Sr ages on biotite and K-Ar ages on biotite and muscovite (blocking temperature around 300°C) are relatively concordant between 12-14 m.y. (JÄGER et al., 1967; PURDY & JÄGER, 1976); Rb/Sr ages on muscovite/phengite (blocking temperature = 500°C) are a little more variable between 16 and 20 m.y.. They are regarded as cooling ages postdating the Lepondine thermal peak (38 m.y. - HUNZIKER, 1970, 1974; JÄGER, 1973) and are undoubtedly the youngest ages Rb-Sr and K-Ar in the Ossola-Tessin area.

The Verampio, Antigorio and Monte Leone orthogneisses outcrop in a north-western, rather external, zone of the Lepondine dome, and their ages point to later uplifting compared with more internal zones. The Antigorio orthogneisses in Tessin show slightly different ages. The few data (for biotite only) give ages around 14-16 m.y., i.e. an earlier uplift compared with the Ossola area. STEIGER and BUCHER (in KÖPPEL & GRÜNENFELDER, 1980) regard the Rb-Sr biotite ages of the cross-biotite bearing

rocks from the southern Gotthard Massif (16-15 m.y.) as crystallization ages corresponding to the last phase of prograde alpine metamorphism. This, however, would postdate the intrusion of the tertiary granitoid rocks: this is not true in the Bergell intrusion since its contact metamorphic aureola overprints regional metamorphism.

The Rb-Sr and K-Ar ages for the Lebendun gneisses agree with those of the Antigorio and Monte Leone gneisses. The micas of the orthogneiss pebbles embedded in conglomeratic gneisses also have alpine ages indicative of complete reequilibration of the Rb-Sr and K-Ar system. The Lebendun Unit, like the other lower Pennidic Units, is well within the staurolite isograd. Persistence at $T > 500^\circ\text{C}$ for a long time may explain the complete rehomogenization of the isotopic systems as evidenced by the very young cooling ages.

U-Pb ages

Here, too, the data are confined to zircons and monazites of orthogneisses (ALLÈGRE et al., 1974; KÖPPEL et al., 1980). The U-Pb ages on zircons do not reflect the alpine event; all are older, between 100 and 250 m.y., except LEB 2 (300-450 m.y.) and SIM 1 (450-500 m.y.). The $^{207}\text{Pb}/^{206}\text{Pb}$ ages are always higher than the U-Pb ages: according to KÖPPEL et al. (1980), this is due to uncertainty of the common Pb correction, the radioactive disequilibrium at the time of crystallization and to analytical errors. As the Alpine event is undeniable, it is clear that the U-Pb ages reflect a drastic lead loss during post-Hercynian times. Even though the U-Pb system on zircons is resistant to complete resetting due to metamorphic events, the Alpine event can have partially opened it. The U-Pb ages for the lower Pennidic orthogneisses thus fail to give a complete account for their prealpine history. On the basis of the upper intercept ages < 340 m.y. on the concordia curve, the Verampio, Antigorio and Leventina orthogneisses are interpreted as Hercynian granites. In Tessin, the Simano gneiss, though similar to the Antigorio, is much older, suggesting Caledonian intrusion age or drastic resetting around 450 m.y. due to anatexis of sedimentary rocks: in this case, the zircons would be inherited. The old age of LEB 2

(augengneiss pebble in metaconglomerate) seems to be its intrusion age or further evidence of drastic resetting around 450 m.y.

On the large scale, a relationship is noticeable between U-Pb zircon age and alpine metamorphism intensity (ALLÈGRE et al., 1974): the younger the age, the higher the intensity. The Simplon Units are younger than the Silvretta nappe (Austroalpine domain) or the Gotthard Massif. On a small scale, this is not true. In Tessin, the Maggia gneisses are older than those of the Ossola area, though the intensity of the Alpine metamorphism was higher.

Only the monazites of the Maggia and Simano nappes (Tessin) have been dated with U-Pb and Pb-Pb methods (KÖPPEL et al., 1980). The ages around 22 m.y. are seen as formation ages of the monazites during the Alpine event, whereas for HUNZIKER & JÄGER they are cooling ages (blocking temperature = 530°C). Furthermore, according to KÖPPEL et al. (1980), the age of 22 m.y. would indicate the end of the medium-grade conditions, owing to the absence of monazites in low grade rocks.

The older ages between 200 and 300 m.y. are more problematic. They may be mixed ages due to partial opening of the U-Pb system in the Alpine time or to the presence of two populations of monazites.

2.2. UPPER PENNIDIC UNITS

Rb-Sr and K-Ar ages

In the upper Pennidic domain, too, dating has been virtually confined to orthogneisses in the Moncucco-Orselina-Isorno Series and in the Monte Rosa nappe (BIGILOGGERO et al., 1982-83; PURDY & JÄGER, 1976; JÄGER et al., 1967; FERRARA et al., 1962; FREY et al., 1976; HUNZIKER, 1970, 1969).

The Rb-Sr whole rock isochron on eight orthogneisses of the Moncucco Series l.s. gives an age of 271.6 ± 4.8 m.y. with an initial isotopic strontium ratio of 0.712 ± 0.0004 (BIGILOGGERO et al., 1982-83). This is regarded as the intrusion age of granites in late-Hercynian time. The strontium ratio points to crustal genesis of the melt. These orthogneisses are thus late-Hercynian granites that underwent the alpine metamorphism.

The Rb-Sr and K-Ar ages for biotites and muscovites are cooling ages postdating the thermal Lepontine peak. The Rb-Sr biotite and K-Ar muscovite data are homogeneous, whereas the Rb-Sr muscovite data range between 25 and 29 m.y., probably due to imperfect correction for the common strontium. The Rb-Sr muscovite isochron gives 36.9 ± 1.7 m.y. (BIGILOGGERO et al., 1982-83) in agreement with the Lepontine metamorphic phase: the strontium i.r. (0.7162 ± 0.0029) indicates that the muscovites are pre-alpine and recrystallized during the alpine event. The Rb-Sr and K-Ar ages for micas of some paragneisses in this Series, also agree with those of the orthogneisses (JÄGER et al., 1967).

The data from some pegmatite samples are more problematic (JÄGER et al., 1967; FERRARA et al., 1962). On one hand, there is a single Rb-Sr biotite age (25.9 ± 5.4 m.y.) that is a little higher than those of the orthogneisses, but still an alpine cooling age; on the other hand, there are some Rb-Sr muscovite ages either around 25 m.y. or 200 m.y. (Montescheno, I Mondei Quarry - Antrona Valley). The latter may correspond to the intrusion age. Triassic pegmatites are unknown in the Central Alps; however, the presence of old ages in a zone within the staurolite isograd where the temperature was $> 500^\circ\text{C}$ requires explanation. Since the oldest ages were found in coarse grained muscovites, it may be that they have much better Sr retention and that the pegmatites underwent a temperature $> 500^\circ\text{C}$ for a relatively short time. The age of 37 m.y., in fact, was obtained from a muscovite isochron. Moreover, the sampling area is quite near the cloritoid-out-staurolite-in isograd, in the western part of the Lepontine dome: the temperature may not have been uniform everywhere.

Old Rb-Sr ages (around 200 m.y.) have also been found on muscovite of the Camughera orthogneisses occurring in the middle and upper Antrona Valley (data in press): this area is nearer to the cloritoid zone but still within the staurolite isograd. The Camughera gneisses show isotopic disequilibria similar to those of the Monte Rosa gneisses. The latter have an age of 310 ± 50 m.y. obtained with the Rb-Sr isochron method on whole rock ($\text{Sr i.r.} = 0.712 \pm$

0.007). This age is interpreted as the formation age of granite. Another isochron on more gneissic orthogneisses gives an age of 260 ± 10 m.y. with $\text{Sr i.r.} = 0.713 \pm 0.004$. HUNZIKER (1970), FREY et al. (1976) consider this age as due to a late-metamorphic phase of the Hercynian event. However, there is no large scale evidence of the Permian metamorphism in the Alps.

Apatite Fission Track - Lower and Upper Pennidic Units

Few data are available. The apatite fission track (FT) ages are cooling ages (WAGNER et al., 1977) when the rock temperature was $120 \pm 20^\circ\text{C}$ during the post-metamorphic cooling process (WAGNER & REIMER, 1972).

The apatite FT ages increase with altitude in the same area. In the Central Alps, the Gotthard and Ossola area show the youngest ages (< 5 m.y.) and were therefore uplifted later than other more easterly zones. On a small scale, the upper Pennidic Units seem to have been uplifted earlier than the lower Units.

Moreover the apatite FT and Rb-Sr ages have been used by WAGNER et al. (1977) to calculate the uplift rate of the Leپontine dome, assuming 30°C/Km as geothermal gradient. Generally speaking, the eastern zones have generally decreased their uplift rate, while the western areas have increased it. On a small scale, the lower Pennidic Units in Ossola accelerated their uplift rate from 0.7 to 1.1 mm/y. about 3 m.y. a. and the upper Units from 0.3 to 0.7 mm/y. about 6 m.y. a., whereas in Tessin the uplift rate decreased from 1.3 to 0.4 mm/y. about 20 m.y. a..

3. Post-collisional Alpine magmatism

3.1. ADAMELLO

The Adamello pluton, the largest Alpine igneous body of Alpidic age, lies at the intersection of two late-Alpine fundamental tectonic lineaments, i.e. the Tonale and the Giudicarie faults. Its Tertiary age was deduced from the geological evidence (CORNELIUS, 1928; BIANCHI & DAL PIAZ, 1937) and has been radiometrically demonstrated by FERRARA (1962), BORSI et al. (1966),

BORSI et al. (1977), DEL MORO et al., (1983 a).

The pluton was intruded discordantly into the Southalpine basement and its Permo-Mesozoic cover after the compressive phase responsible for the large E-W folds immediately W of the massif. The age of this folding is not precisely known. The youngest intruded terrain is the *Dolomia principale* of Carnian-Norian age (BRACK, 1983). The basement consist of metasedimentary rocks showing pre-Alpine metamorphism of chloritoid and staurolite grade followed by a retrogressive overprint in which the contact metamorphism generated new biotite, andalusite, cordierite and sillimanite, in order of increasing temperature (BORIANI & GIOBBI, 1982-83).

Emplacement seems to have taken place through successive inputs of analogous magma associations (gabbro, tonalite, granodiorite, quartzdiorite) starting from the south (M. Re di Castello) 42 m.y. a. and ending 29 m.y. a. in the northeastern sector (M. Presanella) (DEL MORO et al., 1983 a).

The geochemical, petrological and textural characters of the Adamello pluton permit its division into five units:

- 1 - Re di Castello (gabbro, tonalite, granodiorite);
- 2 - Adamello (gabbro, tonalite, leucotonalite);
- 3 - Avio (biotite-tonalite);
- 4 - Corno Alto (trondhjemite);
- 5 - Presanella (hornblende-tonalite and biotite-tonalite).

Each unit displays basic to acidic magmatic fractionation particularly evident in the Re di Castello Unit. The five units share a clear genetic link: evolution of the same primary calc-alkaline basic magma through fractional crystallization and assimilation of crustal material (DEL MORO et al., 1983 b; MACERA et al., 1983).

The first age measurements on this massif were performed by FERRARA (1962) with the Rb-Sr method on a very limited number of samples from the main pluton and the Sostino stock. The ages range from 33 m.y. to 45 m.y. (table 13 a). BORSI et al. (1966) determined Rb-Sr and K-Ar ages of 31 and 30 m.y. on samples from Corno Alto, i.e. the Corno Alto rocks appear to be younger

than most of the tonalites in the rest of the massif (tables 13, 13 a).

Further Rb-Sr and K-Ar radiometric analyses presented by BORSI et al. (1977) at the 5th ECOG in Pisa showed decreasing ages from SW to NE, i.e. from the more basic rocks of M. Re di Castello to the granodiorites-tonalites of Presanella in a range between 52 and 29 m.y.. BORSI et al. (1977) see this as evidence that the pluton formed through a polyphasic magma generation in a layered crust, beginning in the deep crust and continuing at a shallower level.

The most recent K-Ar and Rb-Sr age measurements on micas and amphiboles from Adamello were presented by DEL MORO et al. (1983 a) at the Padua meeting of the Soc. Geol. Italiana (proceedings in press). They corroborate the pattern revealed by BORSI et al. (1977). Nevertheless, more complete sampling and improved analytical techniques have allowed DEL MORO et al. (1983 a) to assign more precise ages to each Unit. There is a general decrease from 42 m.y. (Re di Castello leucoquartzdiorites) to 29 m.y. (Presanella granodiorites) in the NE part of the massif (tables 13, 13 a). The Corno Alto and Sostino Units, also in the NE sector, depart from this sequence, since their Rb-Sr muscovite age of 41-42 m.y. is comparable to that of the M. Re di Castello leucoquartzdiorites.

VILLA (1983) has performed K-Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ determinations on amphiboles from the gabbros occurring at the margin of main units (table 13); the age of M. Mattoni gabbro (the most southerly Unit) is between 49 and 42 m.y., that of the M. Blumone gabbro is 41.7 m.y., and that of the M. Marser gabbro is 37 m.y. (max. age).

DEL MORO et al. (1983 a) have interpreted these ages as intrusion ages. Intrusion was followed by rapid cooling, except that the Corno Alto and Sostino bodies cooled much more slowly owing to their different intrusion history. According to these authors, the age decrease from SW to NE of the pluton can be attributed to a magma source migration, or to northward migration of the fractured zones through which the magma raised up.

One of the more difficult problems in the Adamello geochronology is that of the discordant ages given by the same method for different minerals. In particular, the K-Ar

age of the amphibole is often older than that of the micas. Comparison of the K-Ar and the $^{40}\text{Ar}/^{39}\text{Ar}$ results reveals that the discordance is due to Ar excess in the amphibole. This is attributed by VILLA (1983) to assimilation of the crystalline basement. Since the $^{40}\text{Ar}/^{39}\text{Ar}$ method does not always reveal the amount of the excess argon, the ages must be considered as max. ages.

Summing up, geochronological study of the Adamello pluton has contributed much to its geological reconstruction. According to DEL MORO et al. (1983 a, b), the intrusion sequence is accompanied by a regular increase in the initial $^{87}\text{Sr}/^{86}\text{Sr}$ as well as the $^{18}\text{O}/^{16}\text{O}$, due to an increase in crustal assimilation with time. Northward migration of the intrusive activity towards the Insubric line was a consequence of the extensional tectonics, that followed the compressional regime of the Alpine orogeny.

3.2. VAL MASINO - VAL BREGAGLIA (OR BERGELLER) MASSIF

North of the Insubric Line, at the confluence of Valtellina and Valle della Mera, the Alpine units are intruded by a late-Oligocene calc-alkaline igneous body of predominantly tonalitic and granodioritic composition that extends westwards in a long tail, known as the « San Iorio intrusion »; the « Novate granite » or « San Fedelino granite » is a two-mica leucogranite geographically connected with the Val Masino - Val Bregaglia pluton, but may not be genetically related to the other lithologies (TROMMSDORF & NIEVERGELT, 1983).

The southern part of the massif is dominated by hornblende-biotite tonalite (« serizzo ») with minor ultramafic cumulates and cumulitic gabbros, while the northern and central part consist of a younger, porphyritic biotite-granodiorite (« ghiandone »).

The tonalite is almost concordant in the southern part. Here a true contact aureole cannot be discerned and post-intrusion plastic deformation gives the tonalite a variously pronounced gneissic fabric.

In the northern and eastern parts, cross cutting is clear. There is a distinct contact aureole and only brittle post-crystalline deformation.

These differences reflect a difference in intrusion level. The depth of intrusion increases from NE to SW by at least 8 Km.

The Val Masino - Val Bregaglia intrusion is later than the Le Pontine regional metamorphism. In its easternmost contact aureole, NIEVERGELT & DIETRICH (1977), GAUTSCHI & MONTRASIO (1978) and WENK (1980) have found andesitic-basaltic dykes that are undeformed and crosscut the folded and metamorphosed country rocks, but were affected by contact metamorphism induced by the tonalite intrusion.

The Alpine, post-nappe age of the intrusion was demonstrated by CORNELIUS (1913), who observed that the pluton crosscuts the Alpine Nappe boundaries. A different interpretation was put forward by DRESCHER-KADEN (1940, 1969), ARTUS (1959), WENK (1973, 1983) who attributed the Val Masino - Val Bregaglia pluton to granitization of pre-existing rocks.

Boulders of tonalite are present in the « Como conglomerate », dated as Lower Miocene by PFISTER (1921), Early Oligocene by CITA (1957) and Late Oligocene - Lower Miocene by LONGO (1968) and ROEGEL et al. (1975).

ARMSTRONG et al. (1966) performed Rb-Sr and K-Ar age measurements on biotites of the granodiorite, obtaining values of 24 ± 2.5 and 24.8 ± 1.5 m.y. respect (tables 14, 14 a). JÄGER & HUNZIKER (1969) measured a Rb-Sr muscovite age of 35.5 m.y. and a biotite age of 24 m.y. for the tonalite and granodiorite, while for the « Novate granite » they found 22-24 m.y. and 18 m.y.. This discordance was ascribed to the time elapsed between magma generation and intrusion. The most recent age determination on the Val Masino - Val Bregaglia pluton are those of BORSI (Rb-Sr on biotite), though they have remained unpublished owing to his untimely death.

GRÜNENFELDER & STERN (1960) obtained values of 25 ± 10 and 30 ± 10 m.y. with U-Pb method on two zircons from Albigna. CHESSEX (1964) obtained values of 25 ± 3 m.y. for the « quartzmonzonite » of the northern part and 32-33 m.y. for the « diorite » of the southern part, using the radiation damage method on zircons.

In 1973, GULSON & KROGH analysed zircons, monazites and sphenes from tonalites,

and granodiorites and from the « Novate granite ». The oldest apparent age (65 m.y.) determined on the « Novate granite » was attributed to the presence of an inherited lead component. From the concordant monazite age, and from the lower intercept of a chord joining monazite, zircon and sphene, those workers obtained an age of at least 30 m.y. for the granodiorite crystallization. The intrusion postdates the piling up of the nappes and the main Alpine metamorphism. On comparing the U-Pb monazite and Rb-Sr biotite ages for the same samples, KÖPPEL & GRÜNENFELDER (1975) found that monazite ages are always older: 30 m.y. and 24.8 ± 1.5 m.y. in the Val Masino - Val Bregaglia granodiorite; 26.6 m.y. and 17.7 ± 1 m.y. in the « Novate granite ». According to KÖPPEL & GRÜNENFELDER (1975) the monazite ages of the Le Pontine area do not reflect its cooling history, but the crystallization time under high grade metamorphic conditions: the 30 m.y. monazite age of the granodiorite also represents the time of crystallization of the Val Masino - Val Bregaglia pluton, while the Rb-Sr biotite age (25 m.y.) is a cooling age that fits in well with the cooling pattern of the country rocks W of the pluton.

GULSON (1973) could not find a Rb-Sr w.r. isochron for the pluton and the Novate stock because of the low Rb/Sr ratio (always less than 1), and the young age of the intrusion.

Some granodiorite, aplite and pegmatite samples from the Val Masino - Val Bregaglia rocks and Novate granite gave two reference lines at 65 ± 17 m.y. and 25 ± 80 m.y. resp. (table 14 a).

Two age determinations on Bregaglia granodiorite and Novate granite performed by WAGNER et al. (1977, 1979), with apatite FT, gave 13.5 m.y. and 11.2 m.y. respectively. The importance of apatite FT ages in intrusive and metamorphic rocks, when compared with mica Rb-Sr and mica K-Ar ages (considered as cooling ages), is due to their ability to exhibit the uplift history of a region since the uplift rate is considered to be proportional to the cooling rate (WAGNER et al., 1977).

Later WAGNER et al. (1979) extended their apatite FT age determinations in the Val Masino - Val Bregaglia region and also

dated the boulders of the Como Conglomerate from the pluton. Their aim was to determine the uplift history of the Bregaglia region in comparison to that of the Central Alps and reassign the granitic boulders of the conglomerate to their original vertical position within the Bregaglia granodiorite prior to erosion. Comparison between apatite FT , mica Rb-Sr and mica K-Ar ages for samples collected at different levels of the Bregaglia region showed that the uplift rate of the pluton decreased with time. A similar study of the boulders embedded in Late Oligocene sediments indicated that the body from which they derive must have reached

the erosional surface between 24.5 and 22 m.y. ago.

According to WAGNER et al. (1979) the boulders are derived from an higher, now eroded, part of the pluton, because their apatite FT ages are older than those of the granodiorite now outcropping in the Bregaglia region.

The original elevation of the top of the Bregaglia intrusive body must have been 8 Km higher than at present.

Lavoro eseguito nell'ambito dei programmi del Centro di Studio per la Stratigrafia e la Petrografia delle Alpi Centrali del C.N.R. di Milano.
