## ABSTRACT

The crystal structure of hohmannite,  $\text{Fe}_2^{3+}[\text{O}(\text{SO}_4)_2] \cdot 8\text{H}_2\text{O}$ , was studied by means of single-crystal X-ray diffraction (XRD) and vibrational spectroscopy. The previous structural model was confirmed, though new diffraction data allowed the hydrogen-bond system to be described in greater and more accurate detail. *Ab initio* calculations were performed in order to determine accurate H positions and to support the experimental model obtained from XRD data. Infrared and Raman spectra are presented for the first time for this compound and comments are made on the basis of the crystal structure and the known literature for sulfate minerals.

**KEYWORDS:** hohmannite, crystal structure refinement, *ab initio* calculation, FTIR spectroscopy, Raman spectroscopy.

## Introduction

HOHMANNITE,  $\text{Fe}_2^{3+}[\text{O}(\text{SO}_4)_2] \cdot 8\text{H}_2\text{O}$ , is a hydrous Fe-sulfate occurring in arid environments. It is found typically as a secondary product, associated with chalcantite, metahohmannite, fibroferrite, sideronatrite and copiapite (Palache *et al.*, 1951) and originates from the chemical weathering and oxidation of primary Fe sulfides, such as pyrite or pyrrhotite, owing to bacterial action or to air-oxidation in hydrothermal and magmatic ore deposits (Bandy, 1938). At present there is an increasing interest in the scientific community for the study of Fe sulfates for various reasons. Firstly, Fe-bearing sulfates have been identified recently on Mars, with wide distributions and, locally, in large amounts, using both remote sensing spectroscopic observations and direct-surface explorations by rovers (e.g. Klingelhöfer *et al.*, 2004; Johnson *et al.*, 2007; Vicenzi *et al.*,

2007; Lane *et al.*, 2008; Mills *et al.*, 2013; McCollom *et al.*, 2014). Secondly, these sulfates originate as an intermediate step in a complex series of oxidation, dehydration and neutralization reactions culminating in the precipitation of Fe oxyhydroxides (Jerz and Rimstidt, 2003; Burns, 1987); these processes are associated with AMD (acid mine drainage) and result in the outflow of acidic water from metal- or coal-mine wastes, thus representing a significant environmental concern (e.g. Nordstrom *et al.*, 2000; Welch *et al.*, 2007, 2008, 2009). Iron-sulfate concentrations are common in base-metal deposits, coal deposits, tailings and waste-rock piles, and are related spatially to oxidizing Fe-sulfide minerals. Their considerable solubility causes Fe-sulfate minerals to be found in sheltered sites such as rock overhangs (thereby protected from rain dissolution), or during drier times of the year, as a consequence of the migration of Fe-sulfate solutions to the surface and subsequent evaporation (Jerz and Rimstidt, 2003). Therefore these compounds are sensitive indicators of environ-

\* E-mail: gennaro.ventruti@uniba.it  
DOI: 10.1180/minmag.2015.079.1.02

mental conditions such as pH, relative humidity, oxygen activity and sulfate activity. Hohmannite, together with other metal-bearing sulfates, is, additionally, involved in industrial processes, as a product of the corrosion of carbon steels (Ruhl and Kranzmann, 2012) and as an intermediate product in the treatment of metal residues from hydrometallurgic plants (Ngenda *et al.*, 2009).

Iron-bearing sulfates are difficult to characterize because they occur typically as loose, poorly coherent, powdery masses, making their detection using single-crystal XRD techniques problematic. For this reason, structural investigations on hohmannite are limited. Vibrational spectroscopy techniques are extremely useful in this context (Della Ventura *et al.*, 2013; Ventruti *et al.*, 2013) because they can provide a rapid

identification of the sulfate phase from both powders and single crystals; they are also able to provide a detailed characterization of the degree of hydration of the phase, which is essential for a rigorous interpretation of the hydrologic history of the environment.

To date, no spectroscopic studies have been reported for hohmannite. Its crystal structure was solved firstly by Scordari (1978) starting from a three-dimensional Patterson synthesis, whereas the geometry and positions of the hydrogen bonds were inferred only from geometrical considerations. The aim of the present work is to provide a complete and detailed characterization of the sample studied originally by Scordari (1978) by combining modern XRD with periodic *ab initio* calculations to describe the hydrogen-bonding

TABLE 1. Refined cell parameters and data-collection parameters for the hohmannite sample studied by single-crystal XRD.

<sup>a</sup> =  $[\sum [w(F_o^2 - F_c^2)^2]/(n - p)]^{1/2}$ , where  $n$  is the number of reflections,  $p$  is the total number of parameters refined and  $w$  is the weighting scheme applied;

<sup>b</sup> =  $R_1 = \sum[|F_o| - |F_c|]/\sum F_o$ ;

<sup>c</sup> =  $wR_2 = [\sum[w(F_o^2 - F_c^2)^2]/\sum[w(F_o^2)^2]]^{1/2}$ .

system. Vibrational (Fourier transform infrared (FTIR) and Raman spectroscopy) data are also presented and interpreted on the basis of this improved structural model.

## Experimental

The crystals investigated in this study were handpicked from the same rock specimen as studied by Scordari (1978) from the Sierra Gorda (Chile) deposit; thus the chemical composition is inferred to be the same as that reported in that study. A single crystal selected on the basis of its purity under a binocular microscope was mounted on a Bruker AXS APEXII diffractometer kappa-goniometer equipped with a 1K SMART CCD (charge coupled device) detector with a crystal-to-detector distance of 4 cm. The diffraction data were collected using monochromatic MoK $\alpha$  radiation and frame widths of 0.5° in  $\omega$ , with 30 s acquisition time for each frame. A sphere of three-dimensional data was collected by employing an optimization strategy by the *Apex* program suite (Bruker, 2008) over the interval  $4^\circ \leq 2\theta \leq 76^\circ$ . The three-dimensional data were reduced and corrected for Lorentz, polarization and background effects by means of the Bruker program *SAINT-IRIX* (Bruker, 2008). Empirical absorption corrections were applied to all data on the basis of the intensities of equivalent reflections (Blessing, 1995) by means of the multi-scan method implemented in *SADABS* (Bruker, 2008). The structure refinement was performed in space group  $P\bar{1}$  using the program *CRYSTALS* (Betteridge *et al.*, 2003) starting from the atomic parameters obtained by Scordari (1978). Reflections with  $I > 3\sigma(I)$  were used for the structure refinement. Refined parameters were: atomic positions, atomic displacement parameters and overall scale factor. All atoms apart from hydrogen were refined anisotropically. The hydrogen atoms were located from the difference Fourier maps and refined independently by fixing the O–H distances at 0.85(3) Å and maintaining a dihedral angle H–O–H of  $\sim 104^\circ$ . The isotropic atomic displacement parameters of hydrogen atoms were evaluated as  $1.2 \cdot U_{\text{eq}}$  of the parent oxygen atom. Details on data collection, crystallographic data and refinement are given in Table 1. Atomic positions and displacement parameters for all non-hydrogen atoms are listed in Table 2. The refined positions of hydrogen atoms derived from difference-Fourier syntheses are given in Table 3. Selected interatomic distances are given in Table 4.

The electronic structure of the refined structure was calculated by means of a linear combination of atomic orbitals (LCAO) unrestricted Hartree-Fock (UHF) periodic computational scheme, using the *CRYSTAL09* program (Saunders *et al.*, 2003). For each atom a split-valence basis set was used. Optimization of exponents and coefficients was performed for the Gaussian-type valence orbital of S ions. To facilitate the convergence, the number of the unpaired electrons of Fe $^{3+}$  ions was locked in the first cycles of calculation. The cell parameters and the initial hydrogen positions adopted for each quantum-mechanical calculation were those determined by XRD.

For FTIR powder spectroscopy, samples were prepared as KBr pellets by mixing  $\sim 0.5$  mg of sample, purified under the binocular microscope and verified by XRD, in 150 mg of KBr. Spectra were collected in the 4000–400  $\text{cm}^{-1}$  MIR (mid-infrared) range by co-adding 128 scans with a 4  $\text{cm}^{-1}$  nominal resolution on a Nicolet Magna 760 spectrophotometer equipped with a KBr beam splitter, a globar source and a room-T DGTS detector. Single-crystal FTIR spectra in the NIR (near infrared) range were obtained from a small cleavage fragment,  $\sim 20$   $\mu\text{m}$  thick, using a Bruker Hyperion 3000 microscope, equipped with an MCT (mercury-cadmium-telluride) detector in the 7500–4000  $\text{cm}^{-1}$  range by co-adding 128 scans with a 4  $\text{cm}^{-1}$  nominal resolution.

Single-crystal Raman spectra were obtained using a confocal Horiba Jobin Yvon Labram HR Evolution spectrometer equipped with an Olympus BX41 optical microscope and a multi-channel air-cooled charge-coupled device (CCD) detector. Unpolarized Raman spectra were excited with the He-Ne 632.8 nm line. The laser power was decreased to  $< 1$  mW to avoid potential local heating effects due to heavy light absorption. The sample was inspected optically for any laser damage, and none was observed. Spectra were recorded over the wavenumber range 10 to 4000  $\text{cm}^{-1}$  using an Ultra Low Frequency (ULF) filter. The wavenumber accuracy was  $\pm 0.5$   $\text{cm}^{-1}$ , and the spectral resolution was  $< 1$   $\text{cm}^{-1}$ . Baseline subtraction and peak fitting were performed using *GRAMS/32* software (Galactic Industries Ltd, Salem, New Hampshire, USA).

## The crystal structure of hohmannite

Hohmannite is related to amarantite,  $\text{Fe}_2^{3+}[\text{O}(\text{SO}_4)_2] \cdot 7\text{H}_2\text{O}$  and metahohmannite,  $\text{Fe}_2^{3+}[\text{O}(\text{SO}_4)_2] \cdot 4\text{H}_2\text{O}$  (Bandy, 1938; Strunz and

 FIG. 1. Crystal structure of hohmannite viewed along the *a* axis.

Nickel, 2001; Scordari *et al.*, 2004), and is based structurally on polymerization of centrosymmetrical groups with composition  $[\text{Fe}_4(\text{H}_2\text{O})_8\text{O}_2(\text{SO}_4)_4]$ . These minerals differ chemically in the amount of interstitial  $\text{H}_2\text{O}$  groups, which also result in different packing of the sulfate chains. The structure of hohmannite (Fig. 1), in particular, is characterized by two crystallographically non-equivalent Fe sites, Fe1 and Fe2, surrounded by oxygen and water molecules to form  $[\text{Fe}1\text{O}_5(\text{H}_2\text{O})]$  and  $[\text{Fe}2\text{O}_3(3\text{H}_2\text{O})]$  octahedra, respectively. Two centrosymmetrically related  $[\text{Fe}1\text{O}_5(\text{H}_2\text{O})]$  octahedra share one edge (O13–O13), whereas two additional centrosymmetrically related  $[\text{Fe}2\text{O}_3(3\text{H}_2\text{O})]$  octahedra link to either end of the shared edges. Two symmetrically unrelated  $\text{SO}_4^{2-}$  groups join the Fe octahedral by

corner sharing to form  $[\text{Fe}_4(\text{H}_2\text{O})_8\text{O}_2(\text{SO}_4)_4]$  clusters that polymerize through the O12 oxygen to form complex chains of Fe–O–S linkages running along the *c* axis. Adjacent chains are linked together by hydrogen bonds involving both the four water molecules belonging to the cluster and the four additional interstitial ( $\text{H}_2\text{O}$ ) groups.

The positions of hydrogen atoms found here by difference Fourier (Table 3) confirm that the oxygen atoms O15, O16, O18 and O20 are water molecules linked to  $\text{Fe}^{3+}$  ions, whereas the oxygen atoms O14, O17, O19 and O21 are interstitial water molecules. Inspection of the data shows that all  $\text{H}\cdots\text{O}$  distances are reasonable

Notes: \*  $-x, -y, -z$ 

and that all H atoms are involved in hydrogen bonds (Table 5).

Bond-valence sums were calculated using the electrostatic strength function of Brown and Altermatt (1985) and the bond-valence parameters of Breese and O’Keeffe (1991) for all the non-H atoms refined in the present study, and bearing in mind the H-bond contributions on the basis of the H...O computed distances (Ferraris

and Ivaldi, 1988). Table 6 shows that, excluding the contribution of the hydrogen atoms to the bond-valence calculations, the bond-valence sum (in vu, valence units) for O6, O8 and O11 (1.60, 1.54 and 1.61, respectively) is significantly less than the ideal value of 2 vu. When the hydrogen atoms are included in these calculations, the bond-valence sum becomes much more satisfactory. These calculations confirm that: (1) O6, O8

and O11 are indeed the acceptor atoms for the hydrogen atoms; (2) the interstitial water molecules O14, O17, O19 and O21 act simultaneously as donors and acceptors; and (3) the refined model, as well as the location for the hydrogen atoms, are correct. A reliable hydrogen-bonding scheme according to the converging results obtained from the different techniques quoted above is illustrated in Fig. 2. The bond-valence results are consistent with the previous study (Scordari, 1978) except for some details. In our scheme the O20–H35 hydrogen bond is probably bifurcated because H35 is almost equidistant from both O7 and O9. Finally, unlike the model proposed by Scordari (1978), the O21 water group acts as donors towards  $\overline{O20}$  and O20. These structural data have been tested by making use of the density-functional-based energy minimization calculations. The hydrogen positions found with both techniques are converging (Table 3) even if the calculated O–H bonds (0.95–0.98 Å) are longer than the corresponding ones derived from the difference Fourier map (0.71(2)–0.86(2) Å). These differences are not unexpected and can be explained readily. The theoretical values, in fact, concern distances between nuclear positions, while the experimental values from XRD experiments measure distances between the centroids of the electron density; in

the latter case it is reasonable to expect the electron density of hydrogen to be shifted markedly towards the bonding atom.

### Infrared and Raman spectroscopy

The powder FTIR spectrum of hohmannite in the MIR 4000–400  $\text{cm}^{-1}$  range is displayed in Fig. 3; measured band positions (wavenumbers,  $\text{cm}^{-1}$ ) are listed in Table 7, where the band assignments are based on literature data for similar materials (e.g. Omori and Kerr, 1963; Adler and Kerr, 1965; Bishop *et al.*, 2004; Cloutis *et al.*, 2006; Ross, 1974; Lane, 2007; Della Ventura *et al.*, 2013).

In the higher wavenumber, water-stretching region ( $>2500 \text{ cm}^{-1}$ ) a very broad absorption extending from 3700 to 2800  $\text{cm}^{-1}$  (Fig. 3) is observed; it peaks around 3438  $\text{cm}^{-1}$  with a shoulder at 3234  $\text{cm}^{-1}$ . This broad band is evidently due to the contribution of several overlapping components, including the overtone of the  $\text{H}_2\text{O}$  bending mode ( $2 \cdot \nu_2$ ) expected around 3250  $\text{cm}^{-1}$ . The unpolarized spectrum collected on a single crystal in the NIR range (Fig. 4), shows a relatively broad and intense absorption due to the ( $\nu_3 + \nu_2$ )  $\text{H}_2\text{O}$  combination at 5115–5230  $\text{cm}^{-1}$ . No bands are observed in the 4000–4500  $\text{cm}^{-1}$  range, ruling out any presence

FIG. 2. The hydrogen-bonding system of hohmannite.

## STRUCTURE REFINEMENT OF HOHMANNITE

FIG. 3. Room temperature FTIR powder spectrum of hohmannite in the MIR 4000–400  $\text{cm}^{-1}$  region.

of hydroxyl groups in the structure. The first  $\text{H}_2\text{O}$  overtone ( $2\cdot\nu_3$ ) band is observed as a broad and unresolved absorption centred around  $6920\text{ cm}^{-1}$ .

In the hohmannite structure there are eight independent  $\text{H}_2\text{O}$  molecules (Fig. 2); these are involved in hydrogen bonds of different strengths with the surrounding oxygens (Table 5), thus reducing their local  $C_{2v}$  ideal symmetry (e.g. Nakamoto, 1997). As a consequence, each O–H bond in the  $\text{H}_2\text{O}$  molecule vibrates independently with a frequency related to the local strength of hydrogen bonding. If eight  $\text{H}_2\text{O}$  molecules are considered, 16 asymmetric stretching bands are

expected and these overlap to give the broad pattern of Fig. 3. According to the data of Table 5, in the hohmannite structure the different O–H $\cdots$ O hydrogen bond lengths vary in the range 2.632–3.074 Å. If the empirical  $O_{\text{donor}}\cdots O_{\text{acceptor}}$  distance–frequency correlation of Libowitzky (1999) is considered, bands covering a broad range of frequency are expected, between 3500 and  $3000\text{ cm}^{-1}$ , and this is what is observed (Fig. 3). The  $\text{H}_2\text{O}$  bending mode occurs as a relatively broad absorption centred at  $1636\text{ cm}^{-1}$  (Fig. 3). The Raman spectrum shows a very weak and broad absorption in the water-

TABLE 7. Positions (wavenumber,  $\text{cm}^{-1}$ ) and proposed assignment for peaks observed in the FTIR and Raman spectra of hohmannite.

Infrared	Raman	Assignment
3438, 3234	3495, 3438, 3292, 3204	$\nu_3(\text{H}_2\text{O})$ , $2\cdot\nu_2(\text{H}_2\text{O})$

FIG. 4. Single-crystal unpolarized spectrum of hohmannite in the NIR region.

stretching region (Fig. 5) with two components peaked at 3438 and 3204  $\text{cm}^{-1}$ , and two evident shoulders at 3495 and 3292  $\text{cm}^{-1}$ , respectively.

The powder FTIR spectrum in the low-frequency 1400–400  $\text{cm}^{-1}$  region is given in Fig. 6 in comparison with the Raman spectrum, collected down to 10  $\text{cm}^{-1}$ . It is well known that a free  $\text{SO}_4^{2-}$  ion with ideal  $T_d$  symmetry has four modes of vibration (Table 8): the symmetric stretching  $\nu_1(A_1)$  at 983  $\text{cm}^{-1}$ , the symmetric bending  $\nu_2(E)$  at 450  $\text{cm}^{-1}$ , the antisymmetric

stretching  $\nu_3(F_2)$  at 1105  $\text{cm}^{-1}$  and the anti-symmetric bending  $\nu_4(F_2)$  at 611  $\text{cm}^{-1}$  (e.g. Adler and Kerr, 1965; Ross, 1974). In accordance with selection rules, all modes are either Raman alone or Raman and IR active; there are no IR active only or inactive vibrations. In particular, the  $A_1$  non-degenerate symmetric stretching and the doubly degenerate  $E$  symmetric bending modes are Raman active only, whereas the triply degenerate asymmetric  $F_2$  stretching and bending modes are both Raman- and infrared-active (Table 8). In a solid sulfate structure, however, the arrangement of the surrounding cations causes distortion of the  $\text{SO}_4$  polyhedra away from the  $T_d$  site configuration (Adler and Kerr, 1965; Ross, 1974; Della Ventura *et al.*, 2013). As a consequence of this symmetry reduction, we typically observe in the IR pattern a shift of the absorption bands to different energies, the removal of degeneracy (band splitting) and modification in the spectral activity (appearance of ideally non-active IR/Raman modes).

According to Table 8, where a correlation table for the fundamental vibrations of the  $\text{SO}_4^{2-}$  group in hohmannite, point group  $C_1$ , is presented, 6 IR + 6 Raman bands are expected as both  $\nu_3$  and  $\nu_4$  modes, whereas 2 IR + 2 Raman and 1 IR + 1 Raman bands are expected as  $\nu_2$  and  $\nu_1$  modes, respectively. Examination of Fig. 6 and

FIG. 5. Unpolarized single-crystal Raman spectrum of hohmannite in the full 4000–20  $\text{cm}^{-1}$  frequency range. The  $\text{H}_2\text{O}$  stretching region is magnified in the inset.

FIG. 6. Comparison between the powder FTIR spectrum and the single-crystal Raman spectrum of hohmannite in the low-frequency region.

Table 7 shows that most of the expected bands are indeed present in the spectra although, due to severe overlapping, some of them appear as shoulders only. In the FTIR pattern, four intense bands are observed in the antisymmetric stretching range at 1198, 1134, 1096 and 1052, while two components at 1028 and 1016 occur as symmetric stretching modes. In the Raman spectrum, three weak bands at 1204, 1166 and 1075, and three intense bands at 1125, 1098 and 1058  $\text{cm}^{-1}$  are

present, while the  $\nu_1$  modes occur as an intense doublet at 1031 and 1018  $\text{cm}^{-1}$ . It is to be noted that, although this mode for the  $(\text{SO}_4^{2-})_g$  group is non degenerate (Table 8, see also Adler and Kerr, 1965), the presence of two components in both IR and Raman spectra is in agreement with two independent sulfate sites in the hohmannite structure (Scordari, 1978; this work). The antisymmetric bending modes ( $\nu_4$ ) are strong in the IR spectrum whereas they are very weak in the Raman

TABLE 8.  $\text{SO}_4$  internal mode analysis in hohmannite by the correlation method.

$\text{SO}_4$ internal mode	Free ion point group $T_d$	Site symmetry $C_1$	Space group $P\bar{1} (C_i)$	
$\nu_1$	$A_1$	$A$	$A_g + A_u$	$A_g$ (Raman active)
$\nu_2$	$E$	$2A$	$2A_g + 2A_u$	$A_u$ (IR active)
$\nu_3$	$F_2$	$3A$	$3A_g + 3A_u$	
$\nu_4$	$F_2$	$3A$	$3A_g + 3A_u$	

pattern. The measured Raman range extends at very low wavenumbers ( $\leq 10 \text{ cm}^{-1}$ ) allowing the identification of  $\nu_2(\text{SO}_4^{2-})$ , Fe–O,  $\text{H}_2\text{O}$  and lattice modes, following the assignments from previous studies in the literature on sulfates. The  $\nu_2(\text{SO}_4^{2-})$  modes are observed at wavenumbers  $>400 \text{ cm}^{-1}$  (e.g. Ross, 1974; Knittle *et al.*, 2001; Murphy *et al.*, 2009; Frost *et al.*, 2013) in the Raman spectrum as very intense absorptions (Fig. 6). Vibrational analysis by the application of the correlation method yields six modes that are Raman active ( $6A_g + 6A_u$ ). The unequivocal assignment of these modes is difficult due to the concomitant occurrence in this spectral range of  $\nu_2(\text{SO}_4^{2-})$  and Fe–O,OH modes (Frost *et al.*, 2013; Murphy *et al.*, 2009). Nevertheless, these low wavenumber modes are assigned to the Raman peaks located between 400 and  $227 \text{ cm}^{-1}$ . Finally, Raman peaks that are found below  $200 \text{ cm}^{-1}$  can generally be classified as lattice modes (e.g. Frost *et al.*, 2004, 2013).

## Conclusion

A new and more accurate structure refinement of the rare Fe sulfate, hohmannite, is reported here, where the hydrogen-bonding scheme has been characterized due to improved XRD data, and confirmed by periodic *ab initio* calculations. The first vibrational spectroscopic (FTIR + Raman) data for this phase are also reported. The spectra in the principal  $\text{H}_2\text{O}$  stretching region show a multicomponent broad band in the  $3700\text{--}2800 \text{ cm}^{-1}$  frequency range compatible with the empirical  $\text{O}_{\text{donor}}\cdots\text{O}_{\text{acceptor}}$  distance-frequency correlation of Libowitzky (1999) based on the structure refinement. Comparison with the spectroscopic data found in the literature (e.g. Omori and Kerr, 1963; Adler and Kerr, 1965; Ross, 1974; Bishop *et al.*, 2004; Cloutis *et al.*, 2006; Lane, 2007; Della Ventura *et al.*, 2013) shows that the vibrational spectra of hohmannite, in particular in the low-frequency ( $1400\text{--}440 \text{ cm}^{-1}$ ) region, allow us to distinguish this species from other Fe sulfates. For example, as mentioned above hohmannite may occur associated with amarantite and butlerite. Both FTIR and Raman spectra obtained for hohmannite are significantly different from published spectra of amarantite (Frost *et al.*, 2013) and butlerite/parabutlerite (Cejka *et al.*, 2011). The distinction between hohmannite and metahohmannite based on spectroscopic data is, however, much more subtle. The behaviour of hohmannite at high

temperature has been examined recently and its decomposition products studied by using a combination of thermogravimetric, XRD and FTIR data (Ventruti *et al.*, 2015). The powder FTIR spectrum observed is not significantly modified in the lower-frequency ( $<1300 \text{ cm}^{-1}$ ) region across the hohmannite–metahohmannite transition which occurs at  $\sim 120^\circ\text{C}$  (Scordari *et al.*, 2004, Ventruti *et al.*, 2015). However, the FTIR spectrum in the NIR ( $4000\text{--}5000 \text{ cm}^{-1}$ ) region is extremely sensitive to the modification in the  $\text{H}_2\text{O}$  content of the sulfate phase, and can thus be used to distinguish between these two sulfate compounds. Despite these difficulties we remain convinced that it is worth attempting to improve spectroscopic methods to characterize these minerals.

## Acknowledgements

This work was supported by PRIN 2010–2011 to F. Scordari. The positive criticism of S. Mills, P. Leverett and two anonymous referees helped to improve the manuscript.
