Received 3 June 2013; accepted 14 June 2013

Key indicators: single-crystal X-ray study; $T = 293$ K; mean $\sigma(\text{Si}-\text{O}) = 0.002$ Å; R factor = 0.035; wR factor = 0.083; data-to-parameter ratio = 16.8.

The crystal structure of katayamalite, ideally $\text{KLi}_3\text{Ca}_7\text{Ti}_2(\text{SiO}_3)_{12}(\text{OH})_2$ (potassium trilithium heptacalcium dititanium dodecasilicate dihydroxide), was previously reported in triclinic symmetry ($C\bar{1}$), with isotropic displacement parameters for all atoms and without the H-atom position [Kato & Murakami (1985). *Mineral. J.* **12**, 206–217]. The present study redetermines the katayamalite structure with monoclinic symmetry (space group $C2/c$) based on single-crystal X-ray diffraction data from a sample from the type locality, Iwagi Island, Ehime Prefecture, Japan, with anisotropic displacement parameters for all non-H atoms, and with the H atoms located by difference Fourier analysis. The structure of katayamalite contains a set of six-membered silicate rings interconnected by sheets of Ca atoms on one side and by an ordered mixture of Li, Ti and K atoms on the other side, forming layers which are stacked normal to (001). From the eight different metal sites, three are located on special positions, *viz.* one K and one Li atom on twofold rotation axes and one Ca atom on an inversion center. The Raman spectrum of katayamalite shows a band at 3678 cm^{-1} , similar to that observed for hydroxyl-amphiboles, indicating no or very weak hydrogen bonding.

Redetermination of katayamalite, $\text{KLi}_3\text{Ca}_7\text{Ti}_2(\text{SiO}_3)_{12}(\text{OH})_2$

Marcelo B. Andrade, Donald Doell, Robert T. Downs and Hexiong Yang

Comment

Katayamalite, $\text{KLi}_3\text{Ca}_7\text{Ti}_2(\text{SiO}_3)_{12}(\text{OH})_2$, belongs to the baratovite group of minerals, which includes katayamalite, aleksandrovite [$\text{KLi}_3\text{Ca}_7\text{Sn}_2(\text{SiO}_3)_{12}\text{F}_2$] (Pautov *et al.*, 2010), and baratovite [$\text{KLi}_3\text{Ca}_7\text{Ti}_2(\text{SiO}_3)_{12}\text{F}_2$] (Dusmatov *et al.*, 1975; Fleischer *et al.*, 1976; Menchetti & Sabelli, 1979).

Kato & Murakami (1985) first described the structure of katayamalite with composition $(\text{K}_{0.89}\text{Na}_{0.11})\text{Li}_3\text{Ca}_7(\text{Ti}_{1.95}\text{Fe}_{0.05})(\text{Si}_6\text{O}_{18})_2(\text{OH}_{1.76}\text{F}_{0.24})$ from Iwagi Island, Inland Sea, Ehime Prefecture, Japan, with triclinic symmetry in space group $\bar{C}1$ and unit-cell parameters $a = 9.721$ (2) Å, $b = 16.923$ (3) Å, $c = 19.942$ (3) Å, $\alpha = 91.43$ (10)°, $\beta = 104.15$ (11)°, $\gamma = 89.94$ (10)°. Baur & Kassner (1992), however, proposed that katayamalite is isostructural with baratovite and in fact is monoclinic (space group $C2/c$). By using the transformation matrix (0 1 0/ 1 0 0/ -0.5 -0.5 -1) from the triclinic to the monoclinic setting the unit-cell parameters become $a = 16.923$ (3) Å, $b = 9.721$ (2) Å, $c = 20.909$ (3) Å, $\alpha = 89.98$ (10)°, $\beta = 112.40$ (10)°, $\gamma = 89.94$ (10)°. Recently, aleksandrovite, the Sn analogue of baratovite, was described by Pautov *et al.* (2010) in space group $C2/c$ and with unit-cell parameters $a = 17.01$ (2) Å, $b = 9.751$ (6) Å, $c = 21.00$ (2) Å, $\beta = 112.45$ (8)°. The structure refinement of aleksandrovite has not been reported yet.

The crystal structure of katayamalite is characterized by layers of close-packed six-membered rings of SiO_4 tetrahedra (Figs. 1 and 3). There are six non-equivalent Si atoms in the structure. The silicate layers (T) are connected by sheets of Ca atoms on one side and by an ordered mixture of Li, Ti and K, on the other side, forming a sandwich (Fig. 4) of $T\text{--Ca--}T\text{--}(Li,Ti,K)$ layers. The sandwiches, in turn, are stacked in an *ABAC* packing scheme. The layer of Ca atoms is similar to a brucite layer with its dangling H atoms. The silicate rings are centered by a K atom in one layer, and by an H atom in the other.

The Ca1, Ca2 and Ca3 atoms are eight coordinated and located on general positions while atom Ca4 is 8-coordinated and has $\bar{1}$ symmetry. Li1 lies on a 2-fold rotation axis and Li2 is at a general position; both are tetrahedrally coordinated. The Ti atom is 6-coordinated in form of an octahedron and lies on a general position. The K atom is located on a special position with twofold rotation symmetry; it is 12-coordinated within a distorted coordination environment.

The Si—O bridging bond lengths range from 1.622 (2) to 1.6367 (19) Å, while the Si—O non-bridging bond lengths range from 1.594 (2) to 1.617 (2) Å. The two mean values are 1.629 and 1.604 Å, respectively, while the overall Si—O mean bond lengths is 1.617 Å.

The O—Si—O angles of the six independent SiO_4 tetrahedra range from 101.60 (10)° to 114.59 (11)°; the smallest angle in each tetrahedron is the one involving two bridging oxygen atoms which are bonded to K. The bridging Si—O—Si angles range from 150.52 (15)° to 158.53 (15)° with a mean value of 154.6°.

The H atom was located by Fourier analysis; it exhibits a short O—H distance (0.68 Å). Also, the (O···O) distances are greater than 3.25 Å revealing no or only little hydrogen bonding interactions.

Fig. 5 displays the Raman spectrum of katayamalite. There have been numerous Raman spectroscopic measurements on a variety of structurally related cyclosilicates. A tentative assignment is made according to previous studies, including tourmalines (Alvarez & Coy-Yll, 1978), benitoite (Kim *et al.*, 1993), and joaquinites (Frost & Pinto, 2007). The bands between 900 and 1000 cm⁻¹, and between 1000 and 1200 cm⁻¹ are attributable to the Si—O symmetric and anti-symmetric stretching modes, respectively. The strongest band at 570 cm⁻¹ is ascribable to the Si—O—Si bending. The bands below 500 cm⁻¹ are associated with lattice vibrational modes of Ca—O, Ti—O and K—O. The band at ~3678 cm⁻¹ results from the O—H stretching vibrations, indicating little or no hydrogen bonding (Hawthorne, 1983). The band position is quite comparable to that for other hydroxyl-amphyboles. In fact, the O—H configuration in katayamalite and hydroxyl-amphyboles are remarkably analogous (Figs. 1 and 2).

Experimental

The katayamalite specimen used in this study is from the type locality, Iwagi Island, Inland Sea, Ehime Prefecture, Japan and is in the collection of the RRUFF project (deposition <http://rruff.info/R120164>). Its chemical composition was measured using a CAMECA SX100 electron microprobe (14 analysis points), yielding the empirical chemical formula, calculated on the basis of 38 anions,

(K_{0.89}Na_{0.12})_{Σ1.01}Li_{3.21}(Ca_{6.87}Mn_{0.04}Ba_{0.02})_{Σ6.93}(Ti_{1.79}Zr_{0.14}Fe_{0.04}Sn_{0.02})_{Σ1.99}(SiO₃)₁₂(OH_{1.55}F_{0.45}). The Raman spectrum of katayamalite was collected from a randomly oriented crystal at 100% power on a Thermo Almega microRaman system, using a solid-state 532 nm laser, and a thermoelectrically cooled CCD detector. The laser is partially polarized with 4 cm⁻¹ resolution and a spot size of 1 μm.

Refinement

For simplicity, the ideal chemical formula, KLi₃Ca₇Ti₂(SiO₃)₁₂(OH)₂, was assumed during the refinement. The structure was refined in space group *C*2/*c*, using the coordinates proposed by Baur & Kassner (1992). The maximum residual electron density in the difference Fourier maps was located at (0.4599, 0.5737, 0.1729), 1.49 Å from K and the minimum at (0.2734, 0.5436, 0.1162) 0.62 Å from Si6. The H-atom was located from a difference Fourier synthesis and its position was refined with isotropic displacement parameters and a soft O—H distance restraint. Reflections (2̄02), (2̄44), (242), (7̄12) and (530) were omitted from the refinement due to large differences between calculated and measured intensities.

Special details

Geometry. All e.s.d.'s (except the e.s.d. in the dihedral angle between two l.s. planes) are estimated using the full covariance matrix. The cell e.s.d.'s are taken into account individually in the estimation of e.s.d.'s in distances, angles and torsion angles; correlations between e.s.d.'s in cell parameters are only used when they are defined by crystal symmetry. An approximate (isotropic) treatment of cell e.s.d.'s is used for estimating e.s.d.'s involving l.s. planes.

Refinement. Refinement of F^2 against ALL reflections. The weighted R -factor wR and goodness of fit S are based on F^2 , conventional R -factors R are based on F , with F set to zero for negative F^2 . The threshold expression of $F^2 > \sigma(F^2)$ is used only for calculating R -factors(gt) etc. and is not relevant to the choice of reflections for refinement. R -factors based on F^2 are statistically about twice as large as those based on F , and R -factors based on ALL data will be even larger.
